Palliative care stems from the recognition of the potential at the end of life for discovering and for giving, a recognition that an important dimension of being human is the lasting dignity and growth that can continue through weakness and loss. No member of the interdisciplinary team is more central to making these discoveries possible than the nurse. Realizing how little had been written and even less studied in this field, Peggy Nuttall, a former nursing colleague and then editor of the *Nursing Times* in London, invited me to contribute a series of six articles on the care of the dying in the summer of 1959.1 A registered nurse and qualified medical social worker, I had trained in medicine because of a compulsion to do something about the pain I had seen in patients and their families at the end of life. During 3 years as a volunteer nurse in an early home for such patients, I had persuaded the thoracic surgeon, Norman Barrett, for whom I was working, to follow up a few of his mortally ill patients both there and in their homes. “Go and read medicine,” he said. “It’s the doctors who desert the dying, and there’s so much more to be learned about pain. You’ll only be frustrated if you don’t do it properly, and they won’t listen to you.” He was right and I obeyed. After 7 years’ work, the first descriptive study of 1100 patients in St. Joseph’s Hospice, London, from 1958 to 19651 was coupled with visits to clinical pain researchers such as Harry Beecher in Boston and many U.S. homes, social workers, and nurses in 1963. This visit included an all-important meeting with Florence Wald at Yale. A prodigious program of fundraising letters, professional articles, and meetings led to the opening of St. Christopher’s Hospice in 1967, the first inpatient, home care, research, and teaching hospice. All of those early contacts and countless other interested people led to the hospice movement and the palliative care that developed within and from it.

Nurses were the first to respond to this challenge and remain the core of the personal and professional drive to enable people to find relief, support, and meaning at the end of their lives. All of the expertise described in this important collection is to this end. The window to suffering can be a window

Dame Cicely Saunders, OM, DBE, FRCP

St. Christopher’s Hospice
Syndenham, London
United Kingdom
to peace and opportunity. The nurse, in her or his skilled competence and compassion, has a unique place to give each person the essential message, “You matter because you are you and you matter to the last moment of your life. We will do all we can to help you, not only to die peacefully but to live until you die.”

Dame Cicely Saunders died in July 2005. The editors and all nurses in hospice and palliative care are grateful for her life contributions.

Branford, Connecticut

Nurses of my generation in the second half of the twentieth century were fortunate to be part of the hospice movement and to respond to an eager public with an alternative way of care for the dying. Medical sociologists’ studies of hospital culture showed what many nurses already knew, that when technological intervention failed to stop the course of disease, physicians could not see that the treatment was futile or join the patient in a willingness to cease.

By 1950, nurses began to carry out studies as principal investigators and were on their way to being respected by other disciplines. Two outstanding leaders were Hilde Peplau and Virginia Henderson, both educated nurses in clinical practice who established a foundation for the advanced nurse practitioner to be a valued member of an interdisciplinary team.

This surfaced first in psychiatric nursing, but as hospice care came into being, the nurse became a pivotal part of the interdisciplinary team. “Hospice nursing,” Virginia Henderson said, “was the essence of nursing”; volunteers came quickly into hospice care, proving Henderson’s precept and giving the lay individual “the necessary strength, will, and knowledge to contribute to a peaceful death.”

Physicians in the forefront of medical ethics, such as Edmund Pellegrino and Raymond Duff, encouraged physicians to recast their roles as decision makers and communicators so that the whole team could keep the patients’ values and the families’ wants the prime concern.

The works of those who have brought alternative therapies into use, for example, Martha Rogers and Barbara Dossey, have added to the spiritual dimensions of care. The growth of the religious ministry movement and the creative addition of the arts and environment round out the cast of contributors.

Reviewing the progress we nurses have made allows us to proceed more effectively.
At the end of the Second World War in 1945, people in Western societies were tired of death, pain, and suffering. Cultural goals shifted away from war-centered activities to a focus on progress, use of technology for better living, and improvements in the health and well-being of the public. Guided by new scientific knowledge and new technologies, health care services became diversified and specialized and lifesaving at all costs became a powerful driving force. End-of-life care was limited to postmortem rituals, and the actual caregiving of dying patients was left to nursing staff. Palliative nursing in those days depended on the good will and personal skills of individual nurses, yet what they offered was invisible, unrecognized, and unrewarded.

Thanks to the efforts of many people across the years, end-of-life care is acknowledged today as an important component of integrated health care services. Much knowledge has accrued about what makes for good palliative care, and nurses have been in the forefront of efforts to improve quality of life for patients and families throughout the experience of illness. This book is an acknowledgment of the important part played by nurses in helping patients to complete their lives in a context of care and human concern.
The first edition of *Textbook of Palliative Nursing* was published in 2001. Since that time the field of palliative nursing has evolved quite dramatically.

One major advance has been the extension of the principles of palliative care into all settings of care, as reflected in these pages. Initially found only in hospice units or oncology units, or in settings that focused on the care of individuals with HIV/AIDS, palliative nursing is now practiced in emergency departments, intensive care units, neonatal intensive care units, renal dialysis centers, pediatric care facilities, and many other settings.

In addition, much has happened since the first edition of this textbook to bring long-overdue attention to the area of pediatric palliative care. Of great importance has been the Report by the Institute of Medicine on Pediatric Palliative Care. This second edition of the *Textbook of Palliative Nursing* thus includes an expanded section on pediatric palliative care. This enhanced section includes new chapters on pediatric bereavement as well as care in the neonatal intensive care unit. The authors of these chapters are leaders in the field who have lived the work of caring for children and their families as well as contributed to the evolving literature, research, and model programs. We are greatly indebted to them for their leadership, and hope that this expanded section will be a valuable resource for all nurses in palliative care.

The basic assumptions of palliative nursing—the principles of attention to physical pain and suffering as well as existential distress; inclusion of the family as the unit of care; extension of care into bereavement; interdisciplinary care; and many other basic tenets of the field—are applicable across the very diverse profession of nursing. For this reason we believe that every nurse should be a palliative care nurse. We therefore dedicate this second edition of the *Textbook of Palliative Nursing* to every nurse, for each of us will have the opportunity to provide comfort and compassion to patients in our everyday practice. May we all strive to advance our knowledge and improve the quality of care in serving patients and families faced with serious illness.
About the Forewords

On the previous pages readers will find three Forewords, written for the first edition by three pioneers in the field of palliative nursing: Dame Cicely Saunders, founder of the modern hospice movement; Florence Wald, founder of the first hospice in America; and Jeanne Quint Beneliel, pioneer in psychosocial nursing and the role of nursing in caring for the terminally ill. We have reprinted the Forewords from these pioneers in the second edition because we believe that their legacy is an enduring contribution to all that has come to be known as palliative nursing care. We are indebted to these women and to the many other nurses who have brought the field of palliative care to the forefront, and whose dedication will provide a foundation for us in the future.

Acknowledgments

The editors acknowledge the assistance of Megan Grimm, MPH, who served as our research assistant throughout the process of this second edition. Her commitment and attention to detail were greatly appreciated and are reflected on every page of this text.

Introduction to Palliative Nursing Care

They said there was “nothing to do” for this young man who was “end stage.” He was restless and short of breath; he couldn’t talk and looked terrified. I didn’t know what to do, so I patted him on the shoulder, said something inane, and left. At 7 AM he died. The memory haunts me. I failed to care for him properly because I was ignorant.—A young clinician who later became a palliative care expert

• **Key Points**
  - Palliative nursing reflects “whole person” care.
  - Palliative nursing combines a scientific approach with a humanistic approach to care.
  - The caring process is facilitated through a combination of science, presence, openness, compassion, mindful attention to detail, and teamwork.
  - The patient and family is the unit of care.
  - The goal of palliative nursing is to promote quality of life across the illness trajectory through the relief of suffering, including care of the dying and bereavement follow-up.

“I failed to care for him properly because I was ignorant”—these are haunting words, and they are as true today as they were several decades earlier. Clinicians cannot practice what they do not know. However, the opposite is also true: Individuals and their families, struggling to live in the face of progressive, symptomatic, and debilitating disease, can be well cared for and supported throughout this process and find meaning and peace in the face of death. This is the essence of skilled palliative nursing care—to facilitate the “caring” process through a combination of science, presence, openness, compassion, mindful attention to detail, and teamwork. Although we have both the knowledge and the art to control the majority of symptoms that occur during the last months, weeks, and days of life, we still have much to learn about how to alleviate the psychological and spiritual distress that comes with life-threatening illness.1

Shifting the Paradigm of End-of-Life Care to Palliative Care

Advances in health care have changed the trajectory of dying. Improved nutrition and sanitation, preventive medicine, widespread vaccination use, the development of broad-spectrum antibiotics, and an emphasis on early detection and treatment of disease have resulted in fewer deaths in infancy and childhood and fewer deaths from acute illness.2,3 The combination of a healthier population in many developed countries and effective treatments for disease has resulted in the ability to prolong life. This has led to both benefits and challenges for society. For example, in the United States, more than 70% of those who die each year are 65 years of age or older. The majority of these deaths, however, occur after a long, progressively debilitating chronic illness, such as cancer, cardiac disease, renal disease, lung disease, or acquired immunodeficiency syndrome.
The hospice model of care was developed to address the specific needs of the dying and of their families, so long neglected by the medical system of care. The modern hospice movement started in England in 1967, through the work of Dame Cicely Saunders and colleagues at St. Christopher Hospice in London. The hospice movement came to the United States in the mid-1970s, when Dr. Florence Wald, a nursing pioneer, led an interdisciplinary team to create the first American hospice.5

Hospice care became a Medicare benefit in the 1980s. Patients traditionally followed in hospice programs could no longer receive life-prolonging therapy, and it was required that they be certified by a physician as having a life expectancy of 6 months or less. This presented a problem for patients living with a chronic debilitating disease, whose life expectancy was unclear or was greater than 6 months, or who, for a variety of reasons, did not want to be “identified” as a hospice patient. The palliative care and family-centered care provided through hospice programs was needed, but the barriers presented by the rationing of hospice programs (based on prognosis) and the requirement of denying life-prolonging therapies deprived many individuals of the benefit of such care.

The palliative care model evolved from the traditional hospice perspective to address quality-of-life concerns for those patients living for prolonged periods with a progressive, debilitating disease. It recognized the change in the trajectory of dying in many industrial countries, from that of a relatively short illness leading to death, to one involving a progressive and prolonged debilitating illness frequently associated with multiple factors affecting the quality of life. It recognized that such factors required skilled and compassionate palliative care interventions regardless of prognosis, life-prolonging therapy, or closeness to death. In looking at the relationship between hospice and palliative care, perhaps hospice can best be described as a program through which palliative care is intensified as an individual moves closer to death. Ideally, patients and families living with a chronic debilitating and progressive disease could receive palliative care throughout the course of their disease and its treatment, and as they come closer to death could transition seamlessly and without added distress into a hospice program of care.

The Relationship of Hospice Care to Palliative Care

The hospice model of care was developed to address the specific needs of the dying and of their families, so long neglected by the medical system of care. The modern hospice movement started in England in 1967, through the work of Dame Cicely Saunders and colleagues at St. Christopher Hospice in London. The hospice movement came to the United States in the mid-1970s, when Dr. Florence Wald, a nursing pioneer, led an interdisciplinary team to create the first American hospice.5

Hospice care became a Medicare benefit in the 1980s. Patients traditionally followed in hospice programs could no longer receive life-prolonging therapy, and it was required that they be certified by a physician as having a life expectancy of 6 months or less. This presented a problem for patients living with a chronic debilitating disease, whose life expectancy was unclear or was greater than 6 months, or who, for a variety of reasons, did not want to be “identified” as a hospice patient. The palliative care and family-centered care provided through hospice programs was needed, but the barriers presented by the rationing of hospice programs (based on prognosis) and the requirement of denying life-prolonging therapies deprived many individuals of the benefit of such care.

The palliative care model evolved from the traditional hospice perspective to address quality-of-life concerns for those patients living for prolonged periods with a progressive, debilitating disease. It recognized the change in the trajectory of dying in many industrial countries, from that of a relatively short illness leading to death, to one involving a progressive and prolonged debilitating illness frequently associated with multiple factors affecting the quality of life. It recognized that such factors required skilled and compassionate palliative care interventions regardless of prognosis, life-prolonging therapy, or closeness to death. In looking at the relationship between hospice and palliative care, perhaps hospice can best be described as a program through which palliative care is intensified as an individual moves closer to death. Ideally, patients and families living with a chronic debilitating and progressive disease could receive palliative care throughout the course of their disease and its treatment, and as they come closer to death could transition seamlessly and without added distress into a hospice program of care.

World Health Organization Definition of Palliative Care

In recognition of the changing trajectory of dying and the implications for palliative care, the World Health Organization (WHO) has modified its 1982 definition of palliative care to the following: “Palliative care is an approach to care which improves quality of life of patients and their families facing life-threatening illness, through the prevention, assessment and treatment of pain and other physical, psychological and spiritual problems.”6

The new WHO definition broadens the scope of palliative care beyond end-of-life care and suggests that such an approach can be integrated with life-prolonging therapy and should be enhanced as death draws near. In a similar vein, the National Comprehensive Cancer Network (NCCN) developed guidelines to facilitate the “appropriate integration of palliative care into anticancer therapy.”7 The focus of all these efforts is to change the standard practice of palliative care (identified as “too little, too late”—in which there is a distinct separation between diagnosis, treatment, and end-of-life care—to a vision of the future in which there is “front-loading” of palliative care.8 This means, for example, that at the time of the cancer diagnosis and initiation of treatment the patient would also have access to psychological counseling, nutrition services, pain management, fatigue management, and cancer rehabilitation.8 Such a model is appropriate for other chronic diseases as well. Medicaring, a national demonstration project spearheaded by the Center to Improve Care of the Dying, is an example of an attempt to integrate palliative care into the medical and disease management for seriously ill patients with cardiac and pulmonary disease, who have a life expectancy between 2 to 3 years. The intent is to make this program a Medicare benefit, as is the case with hospice care.8

The Distinctive Features of Palliative Care Nursing

It is useful to define the field of palliative care nursing and to recognize how it differs in essence from other areas of nursing care. In this way, nurses can be educated and trained appropriately, and the special nature of such education and training can be recognized. Palliative care nursing reflects a “whole person” philosophy of care implemented across the lifespan and across diverse health settings. The patient and family is the unit of care. The goal of palliative nursing is to promote quality of life along the illness trajectory through the relief of suffering, and this includes care of the dying and bereavement follow-up for the family and significant others in the patient’s life. Relieving suffering and enhancing quality of life include the following: providing effective pain and symptom management; addressing psychosocial and spiritual needs of the patient and family; incorporating cultural values and attitudes...
into the plan of care; supporting those who are experiencing loss, grief, and bereavement; promoting ethical and legal decision-making; advocating for personal wishes and preferences; using therapeutic communication skills; and facilitating collaborative practice.

In addition, in palliative nursing, the “individual” is recognized as a very important part of the healing relationship. The nurse's individual relationship with the patient and family is seen as crucial. This relationship, together with knowledge and skills, is the essence of palliative care nursing and sets it apart from other areas of nursing practice. However, palliative care as a therapeutic approach is appropriate for all nurses to practice. It is an integral part of many nurses’ daily practice, as is clearly demonstrated in work with the elderly, the neurologically impaired, and infants in the neonatal intensive care unit.

The palliative care nurse frequently cares for patients experiencing major stressors, whether physical, psychological, social, spiritual, or existential. Many of these patients recognize themselves as dying and struggle with this role, which they neither sought nor wanted. To be dying and to care for someone who is dying are two sides of a complex social phenomenon. There are roles and obligations for each person. To be labeled as “dying” affects how others behave toward an individual and how the individual behaves toward self and others. The person is dying, is “becoming dead” (personal communication, Eric Cassell, January 1, 2000), with all that that implies at both an individual and a social level. A feeling of failure and futility may pervade the relationship between the patient and a nurse or physician not educated or trained in hospice or palliative care. They may become disengaged, and the potential for growth on the part of both patient and clinician may be lost—"I failed to care for him properly because I was ignorant . . . the memory haunts me.”

The Palliative Care Nurse and the Interdisciplinary Palliative Care Team: Collaborative Practice

The composition of teams providing palliative care varies tremendously, depending on the needs of the patients and the resources available. The one common denominator is the presence of a nurse and a physician on the team. Regardless of the specific type of palliative care team, it is the nurse who serves as a primary liaison between the team, patient, and family and who brings the team plan to the bedside, whether that is in the home, the clinic, or the inpatient setting. Because of the close proximity of the nurse to the patient and family through day-to-day observation and care, there is often a shift in the balance of decision-making at the end of life from physician to nurse. However, continued involvement of the physician in palliative care should still be fostered and encouraged; it is a myth that the physician need be less involved as the goal of care shifts from cure to comfort. However, a physician oriented toward life-prolonging therapies who has provided care for a given patient over a number of years may feel lost, helpless, overwhelmed, and uncertain of his or her role in the care of the dying; yet, the patient and family may feel very close to that physician and have a great need for him or her at this time. Fear of abandonment by the patient, and the desire of the physician to “do everything” rather than abandon the patient, may result in inappropriate and harmful treatment’s being offered and accepted. A nurse who is educated and trained in palliative care and end-of-life care can do much to guide and support the physician during this transition and to redirect or reframe the interventions from “doing everything” toward doing everything to provide comfort and healing.

There may be other reasons why patients want to continue aggressive, life-prolonging interventions in the face of impending death. Understanding why at times aggressive medical care and life-prolonging measures are sought is an integral part of the role of the nurse on the palliative care team. This is illustrated in the following case example:

Case Study
Mr. Ray, a Patient with Prostate Cancer

Mr. Ray, a 57-year-old man with far advanced prostate cancer and rapidly failing pulmonary status, wanted every measure to be used to maintain life, including a tracheostomy and respirator. He had a wonderful and caring family who wanted whatever he wanted. Staff members felt that they were doing harm by introducing these extraordinary measures but complied with the patient’s wishes. Mr. Ray had fought “the odds” on several previous occasions and expected to do so again. He remained on a respirator for 6 weeks, during which time he was alert and cognitively intact. What the staff did not realize was that during this time the man was completing important work. He sold his business, which he wanted to do before he died so that his wife would not be burdened with this task after his death. Once this goal was completed, Mr. Ray gave his physician the “thumbs up” sign and indicated that he was ready to come off the respirator. The family was at peace with this decision, but the young physician who was responsible for his care and had become very close to the patient and family over the weeks struggled with the concept of prolonging death versus hastening death if the respirator was withdrawn. Some of the nursing staff were similarly troubled. It would have been easier not to have started the treatment than to start and then withdraw it. An experienced palliative care nurse mentored the young physician and nurses through their personal ethical struggles and stayed by the physician’s side as he administered the sedative drug and withdrew the respirator. The patient died 2 days later; a family member was with him all the time. The young physician expressed relief that the patient had not died “right away” and said he felt more comfortable for having “not crossed the line.”
Although other members of the interdisciplinary team, including the chaplain and social worker, were involved with this patient and family’s care and in family and staff “debriefing” and bereavement follow-up sessions, the palliative care nurse played a central coordinating and mentoring role in meeting the needs of the patient, family, physician, and nursing staff. However, no single discipline can meet the needs of most patients and their families; an interdisciplinary team greatly enhances such care.13

How little is known about patients and their families, and their aspirations, is also illustrated in this case. What seems to be an irrational choice to health care providers may be eminently sensible to the patient and family. The frequent struggle and suffering of nurses and physicians as they grapple with their own mortality and with being asked to provide care they think is inappropriate or harmful for dying patients is also demonstrated. Assessment and communication skills, as well as a firm foundation in the ethical principles of palliative care and end-of-life care when treating such patients, are clearly important.

End-of-Life Care in the United States Today: Improving But Still a Long Way To Go

The inadequacy of care for the dying, who are among the most voiceless and vulnerable in our society, came into national focus during the debates over the past decade surrounding physician-assisted suicide and euthanasia. The national dialogue was fueled by the actions of Dr. Jack Kevorkian and his suicide machine; the rulings of two United States Appeals Courts on the right to die14,15; findings from the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT)16; interviews with family caretakers17; a review of end-of-life content in nursing and medical texts18,19 which reflected minimal to no such content; and the Institute of Medicine’s reports on end-of-life care, with its series of recommendations to address deficiencies in care of the chronically ill and dying, both children and adults.2,4

Means to a Better End, a report card generated by Last Acts (a Robert Wood Johnson–funded coalition created with almost 1000 national partner organizations dedicated to end-of-life reform), was the first attempt at a comprehensive report on the state of end-of-life care in the United States.20 Between August 30 and September 1, 2002, slightly more than 1000 Americans were surveyed by telephone and asked their opinions regarding the quality of health care at the end of life. Three quarters of those surveyed had suffered the loss of a family member or close friend in the last 5 years. Each of the 50 states and the District of Columbia were represented in the survey and were rated on eight criteria: state advance directive policies, location of death, hospice use, hospital end-of-life care services, care in intensive care units at the end of life, pain among nursing home residents, state pain policies, and the presence of palliative care–certified nurses and doctors.

The findings suggested that, “despite many recent improvements in end-of-life care and greater public awareness about it, Americans had no better than a fair chance of finding good care for their loved ones or for themselves when facing a life-threatening illness.” For example, nationally only 25% of deaths occur at home, although 70% of Americans say that they would prefer to die at home; about half of all deaths occur in hospitals, but fewer than 60% of the hospitals in any given state offer specialized end-of-life services, and most states have only “fair” hospice use.20 In 2000, there were approximately 3100 hospice programs in the United States, caring for 700,000 patients and their families. Of these patients, more than 50% had a cancer diagnosis, 10% had end-stage cardiac disease, 8% had dementia, 3% had end-stage kidney disease, and 2% had end-stage liver disease.21

Although the state report card measures were very disturbing, activities at the federal, state, and community levels continue to work toward improving access to skilled palliative care and end-of-life care. Some broad examples of these initiatives by professional organizations supported through philanthropic funding include the following:

- Promoting Excellence in End-of-Life Care, a program of the Robert Wood Johnson Foundation that provides grants and technical support to innovative programs throughout the United States to improve care of the dying22
- The End-of-Life Nursing Education Consortium (ELNEC), a national education program to improve end-of-life care23
- The Education on Palliative and End-of-Life Care (EPEC) project, a national program for physicians to improve end-of-life care24
- The pain standards supported by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), which hold institutions accountable for assessment and management of pain among the patients in their care25

In addition, philanthropically supported programs to improve care of the dying have been developed at a community level to meet the needs of specific populations (e.g., the Missoula Demonstration Project26 or underserved communities (e.g., the Harlem Palliative Care Network27). There are also a growing number of palliative care programs being developed within institutions and long-term care facilities, as well as end-of-life pathways and critical care pathways for the dying.28 Home hospice programs that offer palliative care consultation services to the broader patient population are a recent innovation that may improve access to palliative care in nonhospice patients. Board certification in palliative nursing and palliative medicine are also important milestones in recognizing the specific body of knowledge and expertise necessary to practice with competence in this specialty.

Many of these professional, state, and community initiatives address the barriers identified by the National Cancer Policy Board that keep individuals with progressive cancer from receiving excellent palliative care.29 These barriers include
• The separation of palliative and hospice care from potentially life-prolonging treatment within the health care system, which is both influenced by and affects reimbursement policy
• Inadequate training of health care personnel in symptom management and other end-of-life skills
• Inadequate standards of care and lack of accountability in caring for dying patients
• Disparities in care, when available, for African Americans and other ethnic and socioeconomic segments of the population
• Lack of information and resources for the public dealing with end-of-life care
• Lack of reliable data on the quality of life for patients dying of cancer (as well as other chronic diseases)
• Low public sector investment in palliative care and end-of-life care research and training

The National Institute of Medicine Report on improving care at the end of life suggested that people should be able to achieve a “decent” or “good” death—one that is free from avoidable distress and suffering for patients, families, and caregivers; in general accord with patients’ and families’ wishes; and reasonably consistent with clinical, cultural and ethical standards” (p. 24). The report and recommendations focused on the interdisciplinary nature of palliative care, of which nursing is the core discipline. Traditionally, nursing has been at the forefront in the care of patients with chronic and advanced disease, and recent advances in symptom management, combined with the growing awareness of palliative care as a public health issue, have provided the impetus for bringing together this compendium of nursing knowledge.

The general public and the health care community, of which nurses are the largest group, have been confronted with facts about care for the dying and with the task of determining how to achieve quality of life even at the end of life. In December 2001, a consortium of five national palliative care organizations came together in New York because of the identified need to expand access to palliative care for patients and families; to increase the number of reliable, high-quality programs; and to ensure quality. Participants from these organizations were nominated by their peers, with palliative care nursing leadership well represented by Connie Dahlin, Betty Ferrell, Judy Lentz, and Deborah Sherman.

The National Consensus Project for Quality Palliative Care

The National Consensus Project consists of five key national palliative care organizations: American Academy of Hospice and Palliative Medicine, Center to Advance Palliative Care, Hospice and Palliative Nurses Association, National Hospice and Palliative Care Organization, and Partnership in Caring:

America’s Voice for the Dying. The consensus project has five goals: (1) to build national consensus concerning the definition, philosophy, and principles of palliative care through an open and inclusive process that includes the array of professionals, providers, and consumers involved in and affected by palliative care; (2) to create voluntary clinical practice guidelines for palliative care that describe the highest quality services to patients and families; (3) to broadly disseminate the clinical practice guidelines to enable existing and future programs to define better their program organization, resource requirements, and performance measures; (4) to help clinicians provide the key elements of palliative care in the absence of palliative care programs; and (5) to promote recognition, stable reimbursement structure, and accreditation initiatives.

The clinical practice guidelines cover in detail eight domains identified as being crucial to the delivery of comprehensive palliative care: the structure and process of care; the physical domain; the psychological and psychiatric domain; the social domain; the spiritual, religious, and existential domain; the cultural domain; the imminently dying patient; and ethics and the law. The guidelines were released in April 2004 and are outlined in Appendix 1–1.

The Scope and Aims of the Second Edition of the Textbook of Palliative Nursing

Palliative nursing is a world of many connections. To see the world of the individual, a multidimensional, multilens perspective is needed. Often, this complexity is best conveyed through simple stories. This duality of complexity and simplicity is incorporated into the structure of the current and expanded second edition of the Textbook of Palliative Nursing. Each chapter is introduced by a quotation from a patient or family member, to illustrate the content of the chapter. Key Points are included as a quick reference and also as an overview of the chapter content. In addition, brief case examples are used to anchor the theoretical and practical content of the chapter in real-life situations.

The textbook, which includes an international perspective, is intended as a comprehensive resource for nurses in the emerging field of palliative care. The approach has been to incorporate the principles of palliative care nursing throughout the course of a chronic, progressive, incurable disease rather than only at the end of life. The scope is broad. The content, contributed by more than 100 national and international nurse experts and divided into 67 chapters in ten parts, covers the world of palliative care nursing.

Part I provides a general introduction to palliative nursing care and includes an in-depth discussion of hospice care as a model for quality of end-of-life care, the principles of family assessment, and the principles of communication in palliative care. Part II moves into the critical area of symptom assessment and management. Each of the 21 chapters in this section addresses the assessment and pathophysiology of the symptom,
pharmacologic interventions, nondrug treatments, and patient/family teaching within the goals of palliative care. The chapter on complementary and alternative medicine has been greatly expanded, and a chapter on sedation for intractable symptoms has been added.

Part III addresses psychosocial support in palliative care and at the end of life. Here the focus is on the meaning of hope at the end of life, bereavement, family support, and planning for the death and death rituals. Spiritual care and meaning in illness are addressed in Part IV. The impact of spiritual distress on quality of life at the end of life has become increasingly clear, and the ability of the nurse to recognize such distress in patients and their families, and to make appropriate interventions and referrals, is an essential component of palliative care. Much remains to be learned in this area. An addition to this section is a chapter written by a family caregiver that gives a very personal perspective.

In Part V, the needs of special populations and cultural considerations in palliative care are addressed. Included here are the elderly, the poor and underserved, and individuals with AIDS; a new chapter covers care for the drug-addicted patient at the end of life. Part VI focuses on improving the quality of end-of-life care across settings. After a practical overview on monitoring quality and development of pathways and standards in end-of-life care, subsequent chapters discuss long-term care, home care, hospital care, intensive care, rehabilitation, and care in the outpatient or office setting. Additions to this section are chapters on palliative care in the emergency department, palliative surgery, and palliative chemotherapy and clinical trials.

It is with enormous pleasure, and in recognition of the need, that Part VII is entirely devoted to pediatric palliative care across care settings. Part VIII moves into special issues for nurses in end-of-life care and includes ethics, public policy, requests for assistance in dying, nursing education, and nursing research. Part IX explores models of excellence and innovative community projects. International models of excellence are represented here, replacing the international chapters found in the first edition of this textbook. Part X gives voice to the patient and family, exploring the concept of “a good death” through a detailed case discussion. The appendix provides a very comprehensive and useful list of community and professional resources.

The purpose of the Textbook of Palliative Nursing is to organize and disseminate the existing knowledge of experts in palliative care nursing and to provide a scientific underpinning for practice. The focus is on assessment and management of the wide range of physical, psychosocial, and spiritual needs of patients, their families, and staff in palliative care across clinical settings. Topics frequently cited as challenges in nursing care at the end of life—including palliative sedation, communication, ethics, research, and providing care for the underserved and homeless—are specifically addressed. As illustrated throughout, the world of palliative care nursing is complex, scientifically based, and immensely rewarding.

REFERENCES

• Pain, other symptoms, and treatment side effects are managed using best practice.

Domain 2: Physical

• Pain, other symptoms, and treatment side effects are managed using best practice.

Domain 3: Psychological and Psychiatric

• Psychological and psychiatric issues are assessed and managed based on best available evidence.
• Team employs pharmacologic, nonpharmacologic and CAM as appropriate.
• Grief and bereavement program is available to patients and families.

Domain 4: Social

• Assessment includes family structure, relationships, medical decision-making, finances, sexuality, caregiver availability, access to medications and equipment.
• Individualized comprehensive care plans lessens caregiver burden and promotes well-being.

Domain 5: Spiritual, Religious, and Existential

• Assesses and addresses spiritual concerns.
• Recognizes and respects religious belief—provides religious support.
• Makes connections with community and spiritual religious groups or individuals as desired by patient/family.

Domain 6: Cultural

• Assesses and aims to meet cultural-specific needs of patients and families.
• Respects and accommodates range of language, dietary, habitual, and religious practices of patients and families.
• Team has access to/uses translation resources.
• Recruitment and hiring practices reflect cultural diversity and community.

Domain 7: The Imminently Dying Patient

• Team recognizes imminence of death and provides appropriate care to the patient and family.
• As patient declines, team introduces hospice referral option.
• Team educates the family on signs/symptoms of approaching death in a developmentally, age, and culturally appropriate manner.

Domain 8: Ethics and Law

• Patient’s goals, preferences, and choices are respected and form basis for plan of care.
• Team is knowledgeable about relevant federal and state statutes and regulations.

Hospice Palliative Care: A Model for Quality End-of-Life Care

It made me proud that I was able to take care of my loved one at home like we wanted to do for each other. With the help and advice from hospice we were able to do it. I will never regret the time I spent caring for my husband. Sure, there were hard times, but there were also really close times. Hospice helped us prepare together and allowed us some quality time for closure. This experience has given us a sense of satisfaction and our lives more meaning. We learned to cherish each moment and memory we had and enjoy our time together. They really understood his needs as well as mine. We experienced the true meaning of unconditional love from hospice.—Spouse of a hospice patient

Hospice is a program of care provided across a variety of settings, based on the understanding that dying is part of the normal life cycle. As people experience this last phase of life, hospice provides comprehensive palliative medical and supportive services, compassion, and care with the goals of comfort and quality of life closure. A hospice supports the patient through the dying process and the family through the experience of caregiving, the patient’s illness, dying, and their own bereavement. Understanding that the last phase of life is as individual as each person who experiences it, a hospice advocates so that people may live the remainder of their lives with dignity and die in a manner that is meaningful to them.

Instead of asking the patient and family members to fit into a caregiving system, hospice extends services according to their unique situation and values focusing on compassionate care. Compassionate care by its very nature is shaped to fit the individual needs and values of the people involved. Hospice allows the patient and family to direct the services received, rather than having professionals direct the lives of the patient and family. Hospice focuses on the individual's and family's world and encourages personal choices and meaningful experiences concerning the process of illness, dying, and death.

Hospice's unique blend of compassion and skill helps patients and their families deal with life-limiting illnesses and caregiving so that they may (1) live each day with comfort and dignity, (2) retain control over their lives, and (3) discover renewed meaning and purpose in this time of their lives.1

“Family Perspectives on End-of-Life Care at the Last Place of Care,” an article published in the *Journal of the American Medical Association* in January 2004, revealed that the physical and emotional needs of the dying in this country continue to be poorly met, particularly for those who die in institutions. Home-based hospice care received the highest levels of overall satisfaction from respondents in this study. The authors reported that “bereaved family members of patients with home hospice services [in contrast to other settings of care] reported higher satisfaction, fewer concerns with care and fewer unmet needs.”

---

**Key Points**

1. Nurses must understand and honor each patient’s and family’s unique experiences near life’s end, addressing the physical, emotional, and spiritual dimensions of the experience through holistic care guided by what is most important to the patient and family at this time in their lives.
2. Hospice blends compassion and skill to support patients and families through life-limiting illnesses and caregiving, so that they may experience life and relationship completion and closure with dignity and comfort.
3. Hospice care models are expanding to serve people across the lifespan with a variety of services that are helpful from the time of diagnosis of a life-limiting condition through bereavement, including preventive approaches of a public health model.
4. Hospice palliative care services can be provided in all care settings or in the patient’s and family’s home throughout the disease process.
5. Nurses working with the dying and bereaved can experience cumulative loss while finding great meaning and purpose in their work.
The study stated that “high quality end-of-life care results when health care professionals ensure desired physical comfort and emotional support, promote shared decision making, treat the dying person with respect, provide information and emotional support to family members, and coordinate care across settings.” These characteristics of quality end-of-life care are integral to the interdisciplinary hospice philosophy of care.2

Hospice in the United States

Hospice began in the United States as a grassroots effort to improve the quality of the dying experience for patients and their families. Historically, health care delivery systems have been disease driven, with the focus on cure and rehabilitation. Approaches have focused on scientific knowledge of diseases, which drives the care processes. However, approaches to care are different when cure is the goal and when cure is no longer possible. End-stage disease progression and resulting symptoms produce different physiological responses as well as different emotional responses. Hospice care began as a grassroots effort in communities where the traditional medical model fell short of addressing those differences.

The Standards of Practice for Hospice Programs of the National Hospice and Palliative Care Organization (NHPCO) describes palliative care as follows:

- Palliative care is treatment that enhances comfort and improves the quality of an individual’s life during the last phase of life. No specific therapy is excluded from consideration. The test of palliative care lies in the agreement between the individual, his or her physicians, the primary caregiver, and the hospice team that the expected outcome is relief from distressing symptoms, the easing of pain, and/or enhancement of the quality of life. The decision to intervene with active palliative care is based on an ability to meet stated goals rather than affect the underlying disease. An individual’s needs must continue to be assessed, and all treatment options must be explored and evaluated in the context of the individual’s values and symptoms. The individual’s choices and decisions regarding care are paramount and must be followed.1

- Palliative care is considered to be the model for quality, compassionate care at the end of life. Hospice care involves a team-oriented approach to expert medical care, pain management, and emotional and spiritual support expressly tailored to the patient’s needs and wishes. Support is extended to the patient’s family as well. At the center of hospice is the belief that each of us should be able to live and die free of pain, with dignity, and that our families should receive the necessary support to allow us to do so.4

According to National Hospice Foundation research, 80% of Americans wish to die at home. Of the 2.4 million Americans who die each year, fewer than 25% actually die at home. Of the 700,000 patients who received hospice care, more than 75% died at home.4 Hospice programs provide state-of-the-art palliative care and supportive services to individuals who are near the end of their lives, and to their family members and significant others; 24 hours a day, 7 days a week; in private homes, facility-based care settings, or wherever the patient may reside, including acute care settings. Physical, social, spiritual, and emotional care are provided by a medically directed interdisciplinary team (IDT) consisting of patients and their families, professionals, and volunteers during the last phase of an illness, the dying process, and the bereavement period.3

Hospice Palliative Care: A Holistic Approach Focusing on the Experience of the Patient and Family

Understanding the need for a better way to care for the dying, the hospice movement began to provide alternatives to the traditional curative model. Hospice expanded the traditional model, not only to address end-stage disease and symptom management but also to provide for the emotional, social, and spiritual dimensions of the patient’s and family’s illness, dying, and caregiving experiences.

The beginning of the contemporary hospice movement is credited to Dame Cicely Saunders. Beresford5 described her pioneering work as follows: “Her concept of hospice was to combine the most modern medical techniques in terminal care with the spiritual commitment of the medieval religious orders that had once created hospices as way stations for people on pilgrimages.”

The experience of the last phase of life is an individual journey involving one’s mind, body, and spirit. Cassell6 described a theory of personhood whereby each person is a holistic being with dynamic, interrelated dimensions that are affected by the changes and adaptations experienced with progressive illness and dying. These dimensions involve the physical experience of end-stage disease, the emotional experience of one’s relationships, and the way in which one defines spiritual existence.7 As the disease progresses and the physical dimensions decline, the other dimensions (i.e., interpersonal and spiritual) take on added meaning and purpose. What one defines as quality of life changes substantially for people with life-limiting illnesses. Life perspectives, goals, and needs change. It is a time of reflection on a broader sense of meaning, purpose, and relationships, based on each individual’s values.

Hospice grew from this understanding of full personhood; it is designed to offer expert end-of-life care to patients and families that addresses all of these dimensions through an IDT approach. Each patient and family is supported by an IDT consisting of physicians, nurses, social workers, counselors, chaplains, therapists, home health aides, and volunteers. These disciplines reflect the expertise needed to address the varied dimensions that are affected through the course of illness, caregiving, dying, and bereavement.
Hospice Palliative Care: A Model for Quality End-of-Life Care

Aging in the United States and End-of-Life Care

The aging of America has changed the nature and needs of people who are in their last years of life. The Medicare Hospice Benefit (MHB) was designed to provide substantial professional and material support (e.g., medications, equipment) to families caring for dying individuals at home during their last 6 months of life. The benefit was designed for, and lends itself well to, the predictable trajectory of end-stage cancers but not as well to unpredictable chronic illnesses such as congestive heart failure, chronic lung disease, stroke, and dementing illnesses. An examination of hospice care and the delivery of quality end-of-life services must reflect the societal change in aging demographics and the resulting varied needs in end-of-life care models.

In our society, the overwhelming majority of dying people are elderly, and they typically die of a slowly progressing, chronic disease or of multiple coexisting problems that result in multisystem failure. Their final phase of life, which often lasts several years before death, is marked by a progressive functional dependence and associated family and caregiver burden. Hospice programs in demographic areas that represent the future of our aging society, such as Florida, have expanded their care and service options well beyond the original definition of the (MHB) to more fully respond to the frail elderly in their communities who are dying of chronic, progressive illnesses. These expanded hospice delivery models (Table 2–1) are applying hospice philosophy and services in the care of patients and their families throughout the lifespan, long before the last 6 months of life; recognizing the variable dying process; and providing an array of services and intensities of service so that individuals may age in place and stay in their own homes or wherever they choose until death. Hospice, therefore, neither hastens nor postpones death but, rather, affirms life. The focus is on quality of life closure, which begins with the patient’s and family’s definitions of what is most important to them for their remaining time together and is guided by their values, choices, goals, and dreams.

Hospice Palliative Care Philosophy

Hospice philosophy supports the long-term objective of creating a personalized experience with each patient and family at the end of life, whereby in the face of suffering there is opportunity to find meaning, growth, and quality end of life and relationship closure. Promoting quality of life and relationships as well as death with dignity, hospice assists the patient and family to live each day as fully as possible for the remaining time together.

Honoring the Patient’s and Family’s Experience

The experiences of advanced illness, dying, and caregiving have significant and profound effects on both the patient and the family. Therefore, hospice philosophy supports both patient

and family as the unit of care. Family is defined as not only the biological relatives but also those people who are identified by the patient as significant.

Patients and families face many changes and losses during the last years of life. Patients often become concerned about the burden they may cause their family and how their family will survive after they are gone. Families become concerned about how to care for the patient, how to adapt to role changes, their reactions to their losses, and how their lives will change after the death. Families provide varying degrees and types of support, love, and compassion during times of change and crisis. As the patient becomes more dependent on others for care, families become even more significant in this process. Yet, many families have never experienced caring for a loved one who is dying, and many lack the experience of their own losses.

With understanding of the importance of these relationships and family dynamics, patient and family suffering can be minimized and experiences can be enhanced through education, support, and services. Hospice honors the intimate and important role of the family in caregiving and offers resources, education, and support so that family members can be involved in a meaningful way with the care of their loved one.

Hospice philosophy, therefore, promotes the patient and family as a single unit of care. Care does not stop after the death of the patient. Just as the patient’s death experience involves the physical, emotional, spiritual, and social dimensions, survivors’ reactions to caregiving and loss are experienced through the same dimensions. Bereavement-support services are continued for family caregivers for 1 year or longer after the death of the patient, assisting them through bereavement and reintegration to a different life.

Care Is Directed by Patient and Family

Hospice philosophy supports the understanding that dying is the patient’s and family’s experience. Nurses are challenged to approach the hospice care process differently from other situations. Hospice care begins and continues with ongoing facilitated discussions with the patient and family, to discern what is most important to them—their values, choices, wishes, and needs for the remaining life and death. This information becomes the foundation that directs the team in the provision of care and services. Goals become patient- and family-directed rather than nurse directed. It is not about what nurses feel is best but about what the patient and family choose and decide. The care plan becomes the “patient/family care plan,” and the care process is defined by what the patient and family decide is important for this time. A care process directed by patient and family values begins to differentiate the specialty of hospice nursing, with an overall goal of quality of life and relationship closure as defined by the patient and family. This goal is achieved when the patient and family are given opportunities to identify what is most important to completion of their life and relationships, finding meaning in closure, and reaching personal goals before and after the death.

Hospice, Palliative Care, and Curative Care

Hospice is a defined, integrated model of palliative care, which can be as aggressive as curative care, with a focus on comfort, dignity, quality of life/relationship closure, and patient/family choice. Palliative care extends the principles of hospice care to a broader population that could benefit from receiving this type of care earlier in their illness or disease process. Palliative care, ideally, would segue into hospice care as the illness progresses.

Palliative care is most appropriate when it is applied throughout the care continuum, even concurrently with curative approaches if appropriate. A patient receiving curative chemotherapy or radiation therapy could certainly benefit from palliative symptom management. From a psychological and spiritual perspective, patients and their families begin to think about the aspects of life and relationship closure from the time they recognize that the patient has an incurable disease. Emotional and spiritual support from the time of diagnosis, including preparation for remaining life, advancing illness, caregiving, death, and bereavement, creates optimal experiences. When a patient’s disease process is no longer curable or reversible, aggressive curative treatment becomes increasingly inappropriate. An aggressive curative approach to care may actually cause more suffering if cure is no longer possible, or it may simply extend the period of suffering needlessly. As a patient advocate, the hospice nurse is responsible for understanding the differences between curative and palliative interventions, to avoid futile care and prevent unnecessary suffering.

The curative model of care has an inherent problem orientation. Practitioners are often trained to assess and identify “problems” and then determine how to reverse the problem and its effects. Palliative care moves beyond problem identification. The specialty of hospice nursing involves the expert management of end-stage disease symptomatology as a prerequisite to providing the opportunity for patients and families to experience life and relationship closure in ways that are personally meaningful. Hospice expands the traditional disease- and problem-orientated model to a proactive, preventive, quality of life/relationship closure orientation that reflects the full scope of the patient’s and family’s illness, dying, and caregiving experiences.

Through anticipation and prevention of the negative effects of physical symptoms, suffering can be decreased; this allows the patient and family the time and personal resource energy to attend to what is most important for their life and relationship closure. Moving beyond a simple problem orientation, the focus has become one of prevention of suffering and opportunity for growth rather than simply the physical reaction to disease.

A search for meaning and purpose in life is a common experience for people in their last years of life and for their families. From the individual experience of suffering, death can be a time for personal growth, deepening or reconnecting interpersonal and spiritual relationships, and preparing for death and afterlife with enrichment of meaning.
Autonomy and Choice

Hospice philosophy promotes patient and family autonomy in which illness, caregiving, and dying are in accordance with the patient’s and family’s desires. Hospice philosophy strongly believes in patient choice regarding all aspects of living, caregiving, dying, and grieving, including where they will die, how they will die, and with whom they will die. Respecting the patient’s and family’s choices is paramount to quality hospice palliative care.

One of the dying patient’s and family’s greatest concerns is the fear of loss of control. Many losses are anticipated and experienced by terminally ill patients and their families, including loss of bodily functions, loss of independence and self-care, loss of income with resulting financial burdens, loss of the ability to provide for loved ones, loss or lack of time to complete tasks and mend relationships, and loss of decision-making capacity. Dying patients have a right to remain in control of their lives and their deaths. They are often concerned that their wishes will not be honored, that their requests will not be answered, and that, when they are too ill to prevent it, control of their lives will be taken from them. It is critical to provide continued opportunities for choice, input, informed decision making, and the ability to change decisions as situations change.

National Hospice Foundation research shows that the top four services Americans feel are most important for a loved one who has less than 6 months to live are (1) someone to be sure that the patient’s wishes are honored, (2) choice among the types of services the patient can receive, (3) pain control tailored to the patient’s wishes, and (4) emotional support for the patient and family.4

Informed Decisions and Autonomy

Hospice philosophy has been built on the ethical principle of veracity, or truth-telling. Patients’ wishes for information about their condition are respected. Patients and families have the right to be informed about their condition, treatment options, and outcomes so that they can make autonomous, informed choices and spend the rest of their life the way they choose.

Truth-telling is the essence of open, trusting relationships. A sense of knowing often relieves the burden of the unknown. Knowing and talking about diagnosis and prognosis aids in making informed decisions. Patients who have not been told about their illness naturally suspect that something is wrong or being hidden from them, which can result in frustrating, unanswered questions. When patients and families are not told the truth or information is withheld, they can no longer make informed choices about the end of life.

Autonomy results in empowerment of the patient and family to make their own informed decisions regarding life and death. Hospice encourages the discussion of advance directives but does not influence those decisions. Hospice nurses educate on these issues and offer support while the patient and family discuss and choose what is best for them. Their choices may change over time, as the disease progresses, the patient becomes more dependent, or they accomplish their life and relationship closure goals.

When advance directives such as living wills, health care surrogacy, durable power of attorney, and do-not-resuscitate orders are honored, the patient’s wishes are carried out even if he or she is no longer able to communicate or to make health care decisions. With advance preparation, these directives can act in place of the patient’s verbal requests to ensure that her or his wishes are honored. When patient and family members discuss advance directives together, there is often less conflict over decisions and family members are more comfortable supporting the patient’s choices. When advance directives are combined with hospice philosophy, they can serve as preventive measures to ensure that patient’s choices will be communicated, supported, and carried out, avoiding ethical dilemmas. It is critical to provide continued opportunities for choice, input, informed decision-making, and ability to change decisions as situations change. Hospice team members are trained to facilitate personal and family decision-making regarding care, service, and life closure issues. Often, simply having professionals comfortable enough to approach these issues allows patients and families to express their inner feelings, desires, and wishes.

Hospice care supports sensitivity in truth-telling to the degree that the patient and family choose, encouraging open communication among the patient, the family, physicians, and the hospice team. Preparation for death becomes difficult if communication is not open and truthful. With a truthful understanding and freedom of informed choice, patients are more able to control their own living and dying instead of being controlled by the disease or by the treatment plans of others. They can put their affairs in order, say their good-byes, and prepare spiritually in a way that promotes quality and dignity.

Dignity and Respect for Patients and Families

Quality end-of-life care is most effective from the patient and family perspective when the patient’s lifestyle choices are maintained and his or her philosophy of life is respected. Individual patient’s and family’s needs vary depending on values, cultural orientation, personal characteristics, and environment. Dignity is provided when individual lifestyles are supported and respected. This requires respect for ethnicity, cultural orientation, social and sexual preferences, and varied family structures. Hospice nursing requires the provision of nonjudgmental, unconditional, positive regard when caring for patients and families, treating each person’s experience as unique.

Each person and family has individual coping skills, varied dynamics, and strengths and weaknesses. It is our responsibility to accept patients and families “where they are,” approaching living and dying in their own way. Patients and families should be encouraged to express any emotion, including anger, denial, or depression. By listening without being judgmental, the hospice nurse accepts the patient’s and family’s coping mechanisms as real and effective.
Dying patients have their own needs and wants, and hospice nurses must be open to accept direction from the patient. A patient’s focus may include saving all of one’s energy for visits from loved ones, loving and being loved, sharing with others one’s own philosophy of life and death, reviewing one’s life and family history, and sharing thoughts and prayers with one’s family or caregivers. Patients’ goals may include such things as looking physically attractive or intrinsically exploring the purpose and meaning of their lives. Hospice workers’ openness and being prepared to accept and support the patient’s and family’s direction on any given visit helps facilitate and respect their goals. The patient’s and family’s own frame of reference for values, preferences, and outlook on life and death is considered and respected without judgment.

Respecting patients requires hospice nurses to communicate a sense of what is important to the patient and family by ensuring that they express their values and opinions, participate in care planning, make decisions regarding care and how they choose to spend their time, and participate in their own care. Fostering an environment that allows the patient and family to retain a sense of respect, control, and dignity is the foundation of hospice care and services.

The Hospice Nurse as Advocate

Enhancing quality of life and relationships is the primary goal of hospice and palliative care. Patients who, in the later stages of their life, have chosen to receive palliative care have a right to have their wishes honored and respected at all points of entry into and across the health care continuum. Optimizing quality of life and respecting patient’s and family’s wishes involve a great deal of commitment, collaboration, and communication. In promoting patient autonomy, hospice nurses participate as patient advocates across all care settings, supporting the choices and goals that the patient and family have selected for the remainder of their lives.

By integrating the hospice philosophies and values, the hospice nurse acts as advocate for the patient and family, to preserve their rights and protect the goals of their palliative care plan. The hospice nurse’s role of professional advocacy involves collaboration with patients, families, physicians, health care institutions, and health care systems. She or he may be involved in advocating for appropriate symptom management, identifying valuable resources, gaining access to these resources, and coordinating the utilization of resources and services.

The patient, family, hospice IDT, physician, hospice organization, other health and human service providers, and legal institutions are all affected by patient choices. It is the responsibility of every care provider to respect and ensure the rights of dying patients and their families. The services provided by hospice care are what Americans want, yet 83% of Americans do not know about hospice care. Rather than reinforcing their fears about death, it is the nurse’s responsibility to advocate so that every patient and family understands that hospice care provides the compassion and dignity that they want at the end of life.2

Hospice Palliative Care Delivery Systems

Hospice care is not defined by a distinct physical setting or individual organizational structure. It is provided in a variety of settings. Although 90% of hospice patient time is spent in a personal residence, some patients live in long-term care facilities, assisted-living facilities, hospice care centers, or other group settings. In addition, some hospices provide day care programs.8 In 2002, approximately 3200 hospice programs were in existence in the United States. As identified by the NHPCO, the following organizational structures of hospice programs exist, with ever-expanding care and service designs to meet the needs of varied communities:

Free-standing entities represent approximately 50% of hospice programs. Free-standing is defined as being independent of affiliation to a hospital, home health agency, or other care agency.

Hospices affiliated with hospitals are managed as departments or divisions of a hospital or health system. Approximately 31.5% of hospice programs are of this type.

Hospices affiliated with home health agencies represent approximately 18% of hospice programs.10

Expanded Hospice Palliative Care Models

Although hospice appears to add value to end-of-life care, and although it probably does not cost government payers significantly more, the Medicare Hospice Benefit alone is not meeting all the needs of communities for comprehensive high-quality hospice and palliative end-of-life care.11 The most prevalent model of U.S. hospice care, the “Medicare hospice model,” is not viewed as the answer to the challenge of just or equitable access to hospice care nationwide.12 Hospices compatible with this model provide all or almost all of their care within the eligibility requirements and funding parameters of the Medicare and Medicaid hospice benefit; this creates numerous access barriers. These hospice models are much less likely to admit individuals who do not meet Medicare hospice eligibility requirements (i.e., those without a 6-month terminal prognosis and those who do not choose to relinquish all curative care options); they are also less able to admit individuals whose palliative care treatments and medications are costly, although the receipt of costly beneficial palliative care treatment has become increasingly more frequent.13

With the understanding that the Medicare hospice model needs to expand to meet the growing needs for palliative care, hospice programs nationally are developing expanded models. The NHPCO 2004 Facts and Figures report states that more than 60% of hospice programs nationally already have services beyond those outlined in the MHB model.10 Jennings and colleagues12 described two models of hospice care that provide care beyond the Medicare hospice model (Table 2–2). The first of these is the Community Hospice;
Hospice Palliative Care: A Model for Quality End-of-Life Care

Hospice Palliative Care and Service Sites

Private Homes. Encompassing the philosophical principle of autonomy, hospice supports patients and families wherever they choose to live and die. The majority of hospice care is provided in the patient’s private home setting. According to a Gallup poll commissioned by the NHPCO and released in 1996, hospice care coupled with a wish to die at home has widespread support among the public. In perhaps the most striking response in the survey, 88% of those polled said that they would prefer to die in the comfort of their own home, surrounded by family and friends, rather than in any health care institution. Therefore, hospice supports patients’ staying at home until death, if that is where they choose to die.

Source: Jennings et al., 2003, reference 12.

Hospices compatible with this model rely on Medicare hospice revenue but also provide services that reach beyond the Medicare hospice patient to individuals who may not meet the eligibility requirements of the MHB or who do not wish to choose Medicare hospice. However, although the community hospice model is considered superior to the Medicare hospice model, a third form—the Comprehensive Hospice Center model—was believed by Jennings and colleagues to be better for addressing the hospice and palliative care needs of communities. Comprehensive hospices provide all the care and services provided by community hospices, but, in addition, they also have a dedicated academic mission. Considering this, comprehensive hospices are “centers of excellence” for hospice and palliative care.
With so many people choosing to stay at home with family, hospice emphasizes the need to empower families so they may participate in meaningful ways in the care of their loved one. Hospice’s ability to involve the family in caregiving often improves the family’s perspectives and experiences. Research has shown significant differences in favor of hospice in four measures used to evaluate the quality of life of the primary caregiver (family). Primary family caregivers for hospice patients were found to be less anxious and more satisfied with their involvement in care, compared with their nonhospice counterparts.15

Long-Term Care Settings. As the population ages, health care professionals are challenged to provide care and services in different ways. Hospices are increasingly serving elderly people, many older than 75 years of age, who live alone or with a frail family caregiver. As evidenced by the recent expansion of elder care communities, the definition of “home” has also changed for many elderly persons and can include a variety of residential settings with various levels of assistance.

Table 2–3
Benefits of Hospice and Long-Term Care Collaboration

Miller SC, Egan KA (In Press), reference 42.

Hospice seeks to affirm life while ensuring continuity of palliative care in long-term care settings. Some hospice patients are referred while residing in long-term care, whereas others are transferred into long-term care after being served by a hospice program at home. As patient and family needs change at the end of life, hospice home care patients may find long-term care placement a chosen, necessary alternative care setting.

There are many potential benefits to a joint approach and partnership between hospices and nursing homes, but key is the experience of the resident and family as a result of coordinated resources and efforts. The potential benefits of partnership to residents and their families or significant others are detailed in Table 2–3.

Research on the benefits of hospice care in nursing homes has focused on medical dimensions of support. This research has shown that hospice residents, compared to nonhospice residents, experience fewer hospitalizations near the end of life, have fewer invasive treatments (e.g., enteral tubes, intravenous fluids, intramuscular medications), and receive analgesic
management for daily pain that is more in agreement with guidelines for management of chronic pain in long-term care settings. Family members of persons who died in nursing homes perceived improvements in care after hospice admission; they cited fewer hospitalizations and lower levels of pain and other symptoms after hospice admission. Nonhospice residents in nursing homes also appeared to benefit from hospice presence in the nursing home. Nonhospice residents residing in nursing homes with a greater hospice presence (i.e., a greater proportion of residents enrolled in hospice), compared with those in homes with limited or no hospice presence, were less frequently hospitalized at the end of life and more frequently had a pain assessment performed. Considering the cited potential and actual benefits, collaboration seems to be a care alternative worthy of pursuit.

Many hospice programs also have arrangements to admit hospice home patients into long-term care facilities for respite care. Respite care is care for a limited period of time that provides a break for the family while the patient is cared for in another setting. Wherever the patient resides, hospice philosophy can be incorporated and care provided by the full IDT in collaboration with the long-term care staff.

The hospice IDT again advocates and supports autonomy in decision-making by providing information on many alternative care options to the patient and family when home care is no longer appropriate. The hospice nurse and team have the responsibility to educate the family about patient care needs and to respect and support the family's ability to set limits and acknowledge their own needs in placing their loved ones in other care settings.

Assisted-Living Settings. With the aging of the population, there are a variety of elder care living settings in which people may be dying. Recent expansion of adult living facilities (ALFs) has presented the challenge to care for people while allowing them to "age in place" and to "die in place." In the past, facilities licensed as ALFs were required to transfer a resident out of their facility if they could not independently provide care. For many people, this removed them from their home environment as they came closer to death, often resulting in loss of all sense of control over their lives. These residents were prevented from aging in place and dying in place.

Recognizing the detrimental effects of moving people at this time in their lives, residents in ALFs in many parts of the country are now able to stay in the ALF until death, as long as hospice is involved in their care. The end result supports patient autonomy related to where and how the patient chooses to live until life's end. Just as in other care settings, the hospice team remains the care manager in collaboration with the family and ALF staff to advocate for the patient's and family's palliative care goals.

Hospice Residences. Emerging as another alternative setting for people who can no longer stay in their own home is hospice residential care. Residential hospice care refers to the care provided in a facility that is staffed and owned by hospice programs. Patients and their families are given the choice of admission to a hospice residential setting if they are no longer able to care for themselves at home or do not have a caregiver, the caregiver is frail, or the caregiver is working and is unable to provide care at home. Patients may also be admitted to hospice residential care when needs for care (especially highly skilled technical care) are more than the family can manage at home. The same hospice services are available at the residence as in private homes. Family of patients at hospice residences are encouraged to participate in their care to their level of comfort, but hospice staff and volunteers are available 24 hours a day to provide needed care, support, and assistance. The number of hospice residences is growing as communities are realizing their value in filling a care need not provided in the same way in other settings.

Children, adolescents, young adults, and the elderly can be cared for in hospice residential settings. Consistent with hospice philosophy, admittance to residential care should not depend on race, color, creed, or ability to pay. Admission to hospice residences is based on the needs and preferences of the patient and family. Some hospice programs have admission guidelines that restrict their residential care option to those who are closer to death (e.g., within 2 months). However, most programs have found this option of care to be beneficial for many different reasons and have not limited its use or length of stay to a specific time frame.

Hospice seeks to create a community of caring within its residences, striving to be flexible and home-like. Patients may follow their own personal schedule, and their visitors have unlimited access. Patients are usually free to come and go as they please and are encouraged to bring some of their belongings to create an environment that is most comforting to them. The residential setting promotes community and affirms life by offering group activities, group meals, events, and celebrations that promote socialization. Patient choice in participation is respected.

Palliative Care Units. More recently in the United States, hospice programs have created partnerships with acute and long-term care settings to open or manage palliative care units. These units offer a range of services within those facilities, including palliative care consultation, palliative case management, caregiver support and counseling services, and full MHB services. The expertise of acute care professionals coupled with that of hospice professionals allows for the combined benefits of both systems in care of patients at the end of life. Generally, there are patients in palliative care units who are placed there as hospice patients needing acute care interventions or as transfers from the acute care hospital settings, when a transition to hospice care may be beneficial or the palliative care expertise of hospice will be beneficial earlier in the disease progression, before Medicare model hospice services are instituted.

Many people access acute care settings during an episode of exacerbated symptomatology related to an end-stage or chronic disease process. Depending on the response to care and prognostic indicators, patients, families, and physicians begin to realize that conventional curative care may no longer be beneficial or that a combination of curative and palliative care is
optimal. Palliative care units provide an option that allows attention to acute symptomatology by expert end-of-life clinicians while encouraging comfort and dignity for the patient’s and family’s experience. Palliative care units provide the opportunity for a smooth transition from the curative model of care to a palliative model for these patients and families. The advantage for the patient and family is that they are cared for by staff and volunteers who are competent in skilled medical care and end-of-life supportive care.

**Hospital Settings and Hospice.** In addition to inpatient palliative care consultation and case management services, inpatient hospital care is an option for hospice patients and families, usually to meet their acute care needs. Most hospice patients admitted to the hospital setting are considered to be inpatients, as defined by the Medicare levels of care, receiving skilled care. Although most patients prefer to live out the remainder of their lives in their home, there are times when inpatient hospitalization is requested or necessary to meet the changing needs of patients and families.

The reasons for hospitalization can vary. For some patients, the physician may request hospitalization for acute problems, including exacerbation of symptoms that are difficult to control in a home care setting. The patient may also require hospitalization for palliative surgical intervention. At times, hospice patients are admitted to the hospital for a condition that is not related to their terminal diagnosis. Physical needs resulting in hospitalization vary from patient to patient and should be an option in response to patient need and choice.

Some patients may request hospitalization for a fracture repair, whereas others may request to stay at home with medication for pain control. In situations involving possible hospitalization, it is important for the hospice nurse and the IDT to be available to explore with the patient the available choices in care and care setting before hospitalization. The patient and family should also remain involved in the plan of care, to determine how to best meet their changing needs. It is vital that the team provide the patient and family with other available services and care options, to prevent hospitalization if that is their wish.

While assessing the changing needs of patients and families, it is also important that the hospice nurse and IDT support patient and family choice regarding care setting and that they continue to honor the patient’s and family’s requests.

Other population groups receiving hospice care are the homeless and those in prison. These groups have posed challenges for hospice programs to expand service delivery options and provide care in all of these “homes.”

**The Hospice Nurse’s Responsibilities in Facility-Based Care Settings**

Regardless of the type of setting, the hospice nurse and IDT are responsible for continuity of the patient’s and family’s palliative plan of care. When a patient is admitted to a facility, the hospice IDT remains the patient’s care manager. Regulations also require collaborative care planning as well as documentation of mutually developed goals and interventions in some settings (e.g., between long-term care facilities and hospice).

To ensure the highest level of patient and family autonomy, hospice nurses have a responsibility to educate the facility staff about the philosophy, principles, and practices of hospice care. The staff should be able to integrate into their practice a dying patient’s rights and their responsibility in allowing the patient to make his or her own decisions. The specialty of end-of-life symptom management and support of the emotional and spiritual aspects of life closure are still elusive to most nurses; therefore, hospice nurses are often involved in nonhospice settings, educating staff about protocols for pain and symptom management, as well as ways to assist patients and families with the emotional and spiritual aspects of closure of their life and relationships. Education of the staff improves the delivery of palliative care and makes the staff feel more confident and comfortable in caring for dying patients and their families, in contrast to the avoidance that sometimes comes from feelings of inadequacy.

To provide continuity of care, the hospice nurse should be in contact with the facility staff to ensure the patient’s and family’s physical, psychosocial, and spiritual status; their goals and wishes; and that their decisions regarding advance directives are communicated. While respecting the policies and procedures of each setting, the hospice IDT must communicate and collaborate with the patient, family, physician, and facility staff to ensure continuity of the plan of care formulated by the patient and family.

**Hospice Care Provided Through an Interdisciplinary Team**

**The Hospice Experience Model: A Patient/Family Value-Directed End-of-Life Care Model**

Nurses caring for patients and their families at the end of life need to first comprehend the basic differences between curative approaches and palliative end-of-life approaches that honor the unique experiences of patients and families.

Within the foundation of hospice philosophy, one of the significant differences in hospice nursing is the concept that the patient and family direct care, based on their personal values, culture, wishes, and needs. Such issues as dignity and quality can be defined only subjectively, by those who are experiencing life changes associated with illness, caregiving, dying, and bereavement.

The *Hospice Experience Model*, an end-of-life model based on patient/family values, is founded on the following principles that apply to both the patient and family caregivers:

- Illness, caregiving, dying, and bereavement are unique personal experiences.
- People experience the last phase of their relationships and lives through many related dimensions.
The last phase of life and relationships provides continued opportunity for positive growth and development in the face of suffering.

**Principle 1: Illness, caregiving, dying, and bereavement are unique personal experiences.**

Respecting patients' individuality is the foundation of humane care. It requires confronting the fullness of the human context in which illness and aging occur. Individual patients must be the focus of attention, and their particular values, concerns, and goals must be recognized and addressed.22

Just as earlier stages of life for each individual are different, so is dying and end-of-life caregiving. How one adapts to changes brought on as a result of an end-stage disease process or by the normal slowing of systems associated with aging is a very personal response. This response reflects the diversity of an individual's life experience, beliefs, culture, and values. Looking to the future in end-of-life care and understanding the vast differences among individuals who are in the final phase of life, nurses must provide care that results in individualized, customized relationships that respect the values, preferences, and expressed needs of the patient and family in the final phase of life and relationships.

What one person defines as quality of life in the final phase may differ drastically from the next person's definition or differ at points in the life continuum. For one patient, self-determined life closure may mean not being dependent on life-sustaining machines or having a living will. For another patient, it may mean being able to die at home, with family at the bedside. For the patient who has spent the last 3 years confined to a wheelchair, it may involve dying on the screened porch of a mobile home.

The hospice philosophy of care most closely attends to respecting and honoring the individual experiences of caregiving for the family and of illness and dying for the patient. Nurses providing quality end-of-life care must use the guiding principles of autonomy or choice, advocacy, and acceptance to best meet the goal of supporting individualized dying experiences.

**Principle 2: People experience the last phase of their relationships and lives through many related dimensions.**

The caregiving and dying experience is one that affects all dimensions of a person. To comprehend the nature of suffering among the dying, it is essential to know and understand the person. Eric Cassell23 described a model for understanding suffering in his "topology" of personhood. In his multidimensional model of personhood, each person exists as a dynamic matrix of dimensions, or realms, of the self. Each dimension has a significant and dynamic impact on and relationship with the other dimensions. Application of this dynamic relationship of dimensions to the last phase of life can guide the nurse in providing excellence in service and an optimal end-of-life experience for the patient and family.

Ira Byock and Melanie Merriman,24 authors of the Missoula-VITAS Quality of Life Index (the only assessment tool designed to evaluate quality of life closure as an interdimensional, subjective experience of the patient), have developed an end-of-life construct based on Cassell's topology of personhood. The basis for this construct is that people experience the last phase of life as multidimensional beings. As a person's physical and functional dimensions decline, quality of life can be enhanced by attention to their interpersonal, well-being, and transcendent dimensions. Each dimension is briefly described as follows.

**Physical Dimension:** a patient's experience of the physical discomfort associated with progressive illness, perceived level of physical distress; also, caregivers' experience of their physical response to caregiving, which may include fatigue or altered health as a result of the effects of caregiving or the lack of attention to their own health status

**Function Dimension:** a patient's and family's perceived ability to perform accustomed functions and activities of daily living (ADLs), experienced in relation to expectations and adaptations to declining functionality; may include functional ADLs such as bathing, transfer, and feeding, but also includes the expanded aspects of those things that one does to "function" within the social context, such as childcare, paying bills, maintaining a household, and maintaining employment

**Interpersonal Dimension:** degree of investment in personal relationships and perceived quality of one's relations with family, friends, and others; quality of relationships between the patient and others as well as the caregiver and others; from the caregivers experience, this specifically refers to the changes in their relationship with the patient as a result of the illness as well as the anticipated changes in the caregiver's life after the patient's death

**Well-being Dimension:** self-assessment of internal condition, subjective sense of "wellness" or "dis-ease," contentment or lack of contentment, personal sense of well-being, how individuals feel within themselves; may include anxiety, sadness, restlessness, depression, fears, sense of peace, readiness, mindfulness, acceptence

**Transcendent Dimension:** one's experienced degree of connection with an enduring construct; one's relationship on a transpersonal level, which may involve, but does not have to involve, spiritual or religious values; may involve one's perception of the meaning of life, caregiving, suffering, death, and afterlife

Nurses must approach end-of-life care and caregiving with the understanding that a change in one of these dimensions affects the other dimensions. Examining pain as a physical dimension without being prompted to determine how this has affected all of the other dimensions of that person's experience would not attend to the full dying experience. Examining fatigue of a family caregiver as a physical experience alone would not allow us to understand the full experience of the caregiver. In both of these cases, by not examining the experiences from an...
interdimensional perspective, we miss the opportunity to affect the quality of the experience.

An example of a hospice nurse’s assessment of a patient’s pain from an interdimensional perspective is illustrated in the following case study.

CASE STUDY
Mrs. Little, a Patient with Chronic Obstructive Pulmonary Disease

Mrs. Little is having increasing difficulty with breathing at a self-rated level of 4 on a scale of 0 to 10 (physical dimension). She can no longer walk from her bedroom to the kitchen (functional dimension) and is becoming more isolated from family and friends (interpersonal dimension). Mrs. Little becomes anxious just thinking about being alone at night and not being able to catch her breath (well-being dimension). She begins asking God, “Why is this happening to me?” “What did I do to deserve this?” (spiritual dimension).

Continuing with the understanding that hospice cares for the patient and the family, the nurse’s interdimensional assessment of the family (Mrs. Little’s daughter, Goldie, who is her primary caregiver) may be illustrated in the following.

Mrs. Little awakens her daughter several times a night when she gets anxious and feels short of breath, so Goldie is becoming more isolated from family and friends (interpersonal dimension). Mrs. Little misses her friends and coworkers, begins to resent her mother’s demands, and sometimes lashes back at her (interpersonal dimension). At the same time, she feels inadequate and states, “I just don’t know what else to do for her, sometimes I don’t feel very adequate as a caregiver” (well-being dimension). She turns to prayer for her strength to make it through the next day (spiritual dimension).

Referred to as interdimensional care, this approach respects the full scope of the dying and caregiving experience and is the basis for optimally affecting quality of life and relationship closure. The challenge within hospice nursing is to approach all interactions with patients and families with an understanding of this dynamic, dimensional relationship. If this patient’s and family’s situation were approached and assessed from a singular symptom dimension and medical/physical perspective, opportunities to improve the quality of life and relationship closure for the patient and family in all of the other dimensions would be neglected.

When all dimensions are assessed and the patient or family member is able to direct her or his own care and support, an extraordinary possibility for growth, healing, dignity, and positive life and relationship closure can occur. There is opportunity for review, restitution, amends, exploration, development, insight affecting all dimensions, and, therefore, end-of-life and relationship growth.

Family caregivers also experience this phase of their lives through these related dimensions. With so many people choosing to stay at home with family, hospice emphasizes the importance of empowering families so that they can participate to the level they are able in providing care to the patient. In order to understand and honor the family’s experience, it is important not to “take over” the care but instead to provide resources, assistance and support so family members may find the potential for deep meaning and purpose in caregiving and the last phase of their relationship with the care-receiver. Hospice’s ability to involve the family in caregiving often improves family members’ perspectives and experiences. Research has shown significant differences in favor of hospice in four measures used to evaluate the quality of life of the primary caregiver (family). Primary caregivers for hospice patients were found to be less anxious and more satisfied with their involvement in care than were their nonhospice counterparts.  

Principle 3: The last phase of life and relationship provides continued opportunity for positive growth and development in the face of suffering.

In his book, Dying Well: The Prospect for Growth at the End of Life, Ira Byock wrote about the opportunities for growth and development at the end of life. As a hospice physician, he shared his observations of patients and families at the end of life. He explained how people in the face of suffering are able to personally develop a sense of completion, to find meaning in their lives, to experience love of self and others, to say their good-byes, and to surrender to the unknown.

Application of the Hospice Experience Model

Hospice nursing involves incorporating the first two principles of the Hospice Experience Model. Illness, caregiving, dying, and bereavement are unique individual and interdimensional experiences of the patient and caregiver, with life and relationship developmental landmarks and tasks for completion and closure (Table 2–4). The ultimate goal is to provide the opportunity for growth and to improve the quality of life and relationship closure for patients and families as they attend to what is most important to them before the patient dies, through the accomplishment of these life closure tasks.

In addition to the potential for physical distress and suffering, terminal illness presents a final opportunity to complete landmarks and tasks of lifelong development. Quality of life is enhanced as the tasks are completed and the landmarks achieved. Hospice protects and amplifies the opportunity for personal growth in the final stage of life, thereby enhancing quality of life among patients and families.

Dying is a part of living. The period of time referred to as dying can be considered a stage in the life of the individual
person and the family. Developmental psychology involves the study of life stages and the related tasks to be accomplished and opportunities for growth associated with each stage. Within our current culture, there seems to be an assumption that, once a terminal diagnosis has been given, meaningful life has ended—yet dying and end-of-life caregiving are specific stages with related growth tasks and accomplishments.

As reflected in *The Quest to Die with Dignity: An Analysis of Americans’ Values, Opinions and Attitudes Concerning End-of-Life Care*, people tend to see the last phase of life as one of awaiting death, hoping minimally for some measure of comfort and not being a burden to others. This limited perspective devalues and separates this last stage of life from the continuum of a person’s existence while minimizing hopes and goals. Hospice professionals have learned differently from patients and families, and the Hospice Experience Model integrates those lessons by incorporating the framework for life and relationship closure.

Byock conceptualized dying as a stage of the human life cycle that inherently holds opportunities to broaden the personal experience, determine “what matters most,” influence the outcome for improved quality of life closure, and, in so doing, reveal new sources of hope. He believes that individuality extends through the very end of life, characteristic challenges and meaningful developmental landmarks can be discerned, and representative tasks toward the achievement of goals for life completion and life closure can be identified. Byock elucidated the opportunity, during this last phase of life, for uncovering new or deeper sources of meaning in people’s lives.

lives and in their dying. It is important that a developmental approach to the end of life not be misconstrued as a set of prescribed requirements. Rather, these landmarks and tasks can become part of a conceptual framework in which to approach end-of-life care processes, systems, and relationships. They can provide a common language and common approaches to ensure patient/family value-directed care that optimizes quality of life and relationship closure. How each patient and family chooses to attend to or accomplish these tasks will be specific to what is most important to them at this time in their lives, as reflected by their values, goals, and needs.

The developmental landmarks and task work for life completion and life closure that Byock defined provide direction for care in the final phase of life (Table 2–4). They reflect the gradual process of life transition from worldly and social affairs, to individual relationships, and to intrapersonal and intrapsychic affairs

transcendent dimensions. In a landmark national research project, *Caregiving at Life’s End*, a national needs assessment of hospice family caregivers confirmed the hypothesis that family caregivers also experience these aspects of completion and closure (Table 2–5), and the more they experience these aspects, the greater gain they have in the end-of-life caregiving experience. What was also learned was that the more caregivers feel they can have an impact on the life closure aspects for the care-receiver, the more meaning they themselves find in the experience of caregiving. The aspects of completion and closure are closely interrelated for the patient and family caregiver, as illustrated in case examples shown in Table 2–6.

These tasks and landmarks can offer a guide for professionals caring for patients and families in the last years of life. By first opening dialogue about the possibility of meaningful experiences related to these landmarks and tasks, we acknowledge and validate the patient’s and family’s experience. As with other developmental stages in life, developmental tasks are best accomplished with optimal interventions and in a supportive environment. As with a toddler who is learning to walk or talk, a safe, encouraging, and nurturing environment is essential to safe accomplishment of these tasks. The hospice approach to the relationships among the patient and the family or other caregivers becomes one of providing interventions that create optimal, safe, nurturing environments to facilitate work on life and relationship closure tasks to the extent that they choose, are interested, and are able to engage.

As nurses, we have the responsibility to attend to the physical and functional dimensions of care while supporting issues of life closure in the other dimensions so that patients and families can accomplish the end-of-life developmental landmarks to the extent that they choose. Accordingly, the hospice nurse’s initial role in end-of-life care is to work with the patient and family to prevent or minimize the suffering that results from the physical and functional decline of advancing age or from end-stage disease progression. It is after these dimensions are addressed and managed that the patient and family can attend to life- and relationship-closure tasks and landmarks that they feel are important and that involve the interpersonal, well-being, and transcendent dimensions of their experiences.

Although each patient approaches these landmarks and associated tasks in his or her own way, there are some common aspects. Generally, patients first accomplish the few landmarks or tasks that relate to separating from and settling worldly affairs and community relationships, before the tasks involving moving away or separating from friends and family and, finally, those tasks marked by introspection. As people get closer to death, it is common to observe a gradual withdrawal from worldly relationships, friends, and family as they begin the transition on their individual journey from life to death. The nurse’s goal is to explain and normalize this experience, thereby recruiting the IDT and family members to help preserve the patient’s and family’s opportunities to experience peace and comfort within themselves during their personal encounter with illness, caregiving, death, and bereavement.

Salmon and colleagues confirmed the positive aspects of caregiver relationship closure through their research with hospice family caregivers. They found that hospice family caregivers did the following:

- Indicated that they want practical information about caregiving, such as information that helps them to understand the illness, know how to give medications, make end-of-life decisions, communicate with health care professionals, and give hands-on care.
- Valued and felt comfortable with tasks such as understanding the illness and giving medications.
- Wanted to know what to expect at the time of death.
- Experienced greater caregiver gain when comfortable with what are known as the transformative tasks of caregiving—finding meaning and purpose, feeling closure, and self-acceptance.

These results support the principle of opportunity for gain and positive experiences in the face of suffering and clearly indicate the unique value of hospice services for family caregivers.

**The Experience of Illness and Dying: Nursing Process from a Hospice Perspective**

Hospice nursing involves three broad areas: (1) approaching care from a patient- and family-based, interdimensional care focus, as described earlier; (2) expertise in end-stage disease and symptom management; and (3) applying the nursing process as a member of the hospice IDT through a critical thinking approach that supports the Hospice Experience Model.

End-stage disease and symptom management present a unique challenge for many nurses when they begin hospice nursing. This challenge involves incorporating norms for disease progression and symptom management different from those applied in a curative model. Symptoms that are considered abnormal in a curative approach may become the expected norm for a person who is dying.

Pharmacological interventions for pain and symptom management are emerging as a body of knowledge that has not yet been integrated well into the nursing curriculum. Nonpharmacological interventions that are considered appropriate for a patient on a curative path may actually increase suffering for a patient who is dying. An example may be encouraging intake of food and fluids. For a curative approach, this is appropriate to increase strength and healing. When a patient approaches death, however, the body’s systems are slowing. This slowing results in a decreased caloric requirement as well as a slowing of fluid perfusion. By forcing food and fluids, we could increase the demands on the gastrointestinal and circulatory systems, thereby creating increased discomfort. It becomes the
### Table 2–6
Interrelatedness of Care-receiver and Caregiver Tasks

<table>
<thead>
<tr>
<th>Care-receiver and Caregiver Tasks</th>
<th>Example of Interrelatedness (see Tables 2–4 and 2–5)</th>
</tr>
</thead>
</table>
| **Care-receiver:** Sense of completion with worldly affairs  
- Transfer of social responsibilities  
**Caregiver:** Life affairs  
- Transfer of knowledge and/or responsibility  
- Advocacy of care-receiver’s wishes | **Care-receiver:** Mr. Kent, the patient, wants his son (caregiver) to have power of attorney to manage his wife’s financial accounts. Mrs. Kent has dementia, and he is concerned about having money available for her continued care after he dies.  
**Caregiver:** Mr. Kent, an only child, does not want his dad to worry. He is willing to be the primary caregiver for his mother after his dad dies. He knows he will need to be able to manage the family money so that it is available for her care at home if he must hire additional help or if he needs to place her in a long-term care facility. |
| **Care-receiver:** Sense of completion in relationships with community  
- Closure of multiple social relationships  
- Expression of feelings  
- Leave-taking  
**Caregiver:** Relationships with community  
- Changes and/or closure in multiple social relationships  
- Expressing feelings  
- Maintaining connections | **Care-receiver:** Mr. Jay wants to sell his business to his partner, because he can no longer attend to the clients.  
**Caregiver:** Mrs. Jay does not want the business to be sold, especially because her husband worked so hard to make it successful. She was employed in the business until her spouse got very sick and could no longer care for himself. She feels she lacks some of the skills to be a partner but could learn. She is hesitant to ask her husband about it, because he is so ill. She very much wants to spend time with her husband right now and has no time to attend to work. She feels she is losing both her husband and the family business. |
| **Care-receiver:** Sense of meaning about one’s individual life  
- Life review  
- Telling “one’s story”  
- Transmission of knowledge and wisdom  
**Care-receiver:** Sense of completion in relationships with family and friends  
- Reconciliation, fullness of communication, and closure  
- Expression of feelings  
- Leave-taking  
**Caregiver:** Personal relationships  
- Facilitating the life review  
- Acceptance of transmission of knowledge and wisdom  
- Reconciliation of conflicts  
- Open, honest communication  
- Expression of feelings | **Care-receiver:** Mrs. Thomas is widowed and lives alone on the family farm. She has two daughters, both living in distant cities, having left the state for college, started careers, and seldom returned to the family home. When Mrs. Thomas became bed bound, her daughter, Judy, came to care for her and intends to share the caregiving with her sister. Mrs. Thomas tells stories about the girls’ childhoods, trying to understand what she did to make her children want to leave the farm. She also tells stories about her own childhood and growing up on the family farm, her fame as the best cook in the county, and her willingness to take in stray animals. Judy is a successful corporate lawyer. Mrs. Thomas feels the need to relay to her daughter that success is not measured by money but by being “good to all creatures great and small.”  
**Caregiver:** Judy has taken a leave of absence from work to care for her mother for a month. She is very concerned about her job and corporate clients while she is away. When Judy returned home, she noticed the peace and quiet of her family home. As her mother told stories about her life and raising her and her sister, Judy realized how little she knew about the family tree and family history. She began to ask other questions about the family. As her mother provided advice about success and felt such accomplishment in what Judy considered “little things,” Judy began questioning her own accomplishments and whether they really made a difference in anyone else’s life. She began to examine her role as a caregiver and the difference it was making in her mother’s life. |

Interrelatedness of Care-receiver and Caregiver Tasks (continued)

<table>
<thead>
<tr>
<th>Care-receiver and Caregiver Tasks</th>
<th>Example of Interrelatedness (see Tables 2–4 and 2–5)</th>
</tr>
</thead>
</table>
| **Care-receiver:** Experience of love of self  
  • Self-acknowledgment  
  • Self-forgiveness  
  **Care-receiver:** Experience of love of others  
  • Acceptance of worthiness  
  • Acceptance of forgiveness  
  **Care-receiver:** Sense of a new self beyond personal loss  
  • Acceptance of new definition of self  
  • Acknowledgment of the value of that new self  
  **Caregiver:** Experience of love of self and love of others  
  • Acknowledgment  
  • Forgiveness |
| **Care-receiver:** Acceptance of the finality of life  
  • Acknowledgment of personal loss  
  • Expression of the depth of personal tragedy that dying represents  
  • Decathexis and cathexis  
  • Acceptance of dependency  
  **Care-receiver:** Surrender—“letting go”  
  • Will to die  
  • Acceptance of death  
  • Saying good-bye  
  • Withdrawal from family, friends, and professional caregivers  
  **Caregiver:** Acceptance of the finality of life  
  • Acknowledgment of personal loss/tragedy  
  • Anticipatory grief |
| **Care-receiver:** Mrs. Snider is dying from breast cancer, and her husband is her caregiver. Their son died when he was 4 years old; he drowned in the backyard pool while in her care. She was never able to forgive herself for the death of her son, and she believes her husband never really forgave her in the 50 years they have been together since that awful time. He grieved hard, and he punished her for her son's death by never really letting go of the grief. She feels she missed life because of her guilt and her husband's grief. With the help of the chaplain, Mrs. Snider has been able to forgive herself for her son's death, and she is glad that after death she will be reunited with him. She also realizes that her love of her husband allowed him to stay a shut-in, because she did not want to hurt him any more by leaving him. She only wishes he could forgive her. She did the best she could, and that is worth something.  
  **Caregiver:** After the death of his son, Mr. Snider felt he had no other reason to live. His legacy was gone, and he and his wife could not have any other children. They were so grief-stricken that he felt the need to protect both of them from the outside world, which became a lifelong pattern. They depended on each other for everything, never asking for help and never socializing with anyone. Since he lost his son, he has had difficulty loving anyone for fear he would lose them. Now he is losing his wife. Even though he tried not to love her for not being there when his son fell into the pool, he finds he still loves her. For the past 50 years, however, he has not shown his love to her. He also did not know he could care for anyone the way he has been able to care for his wife throughout this illness. The chaplain who visits is helping him feel better. He realizes that his grief filtered down to his relationships, and that it was okay to miss his son. He feels he had no right to punish his wife for this long; holding onto her so tightly to keep from losing someone else was not intentional and was a sign of love. Could she ever forgive him? He needs to show her his love and ask her forgiveness for his past actions. He is worried about life without her—he will have no one if he doesn't act now. Perhaps he will call his sister to help. |

(continued)
General Principles

- Acknowledgment and/or acceptance of the care-receiver’s impending death
- Letting go—acceptance of care-receiver’s withdrawal
- Closure of relationship with care-receiver

Care-receiver: Sense of meaning about life in general
- Achieving a sense of awe
- Recognition of transcendent realm
- Developing/achieving a sense of comfort with chaos

Caregiver: Meaning of life
- Achieving a sense of awe
- Attending to the spiritual elements
- Acceptance of constant changes in life, growth in experiences
- Sense of meaning and purpose as a caregiver and in life

Note: The care-receiver and the caregiver usually do not go through this stage at the same time. The care-receiver usually finds meaning in life before he or she dies, whereas the caregiver may not find meaning in life until after the death, sometimes as a result of paralleling the care-receiver’s journey and observing him or her make sense of death and look to the unknown with comfort. The care-receiver finds comfort with the chaos that surrounds dying, whereas the caregiver realizes after the death that change is constant, that it is still affecting him or her, and that growth can result from change. In addition, while the care-receiver’s focus becomes death, the caregiver’s focus becomes one of life—a sense of awe about life, a new-found appreciation for life, a purpose in life (possibly a feeling of connectedness between this world and the next or between the self and a higher power or the universe). The caregiver may also find spiritual peace as he or she begins to feel that everything is connected, that there is meaning and purpose in caregiving and in life.

Care-receiver: Fred’s health was declining rapidly. He became weaker and slept more. He was not eating and was taking only sips of fluids. He felt as though there was nothing more to do, nothing more to say, and he somehow accepted death. He was comfortable with who he was and what he had accomplished. He felt in awe about life and what a wonderful gift it was to be able to live, but he also sensed that there was something greater, something beyond this place. While his daughter was running around and fretting about her job, her income, how much she had to do, and managing all his care and the community services he received, he found himself relaxing and actually trying to comfort her. He thought she was dumbfounded by how calm he was about dying. He was not sure he even knew why he was so calm, except that he knew there was nothing more he could do or had to do, and he instinctually felt that there was something beyond this world, something waiting for him, someone waiting for him. He hoped it was his wife and his favorite dog.

(continued)
responsibility of any nurse caring for patients at the end of life to gain specific knowledge and competence in end-stage disease and symptom management.

**Critically Thinking Through the End-of-Life Nursing Process**

Illness, caregiving, suffering, dying, and bereavement evoke many interdimensional changes and reactions for both the patient and the family. By looking at the patient and family from this perspective, we begin to move away from a traditional, problem-oriented approach to a quality-of-life and relationship closure–oriented approach. All of the care processes and tools must therefore prompt a different critical thought process.

Each step of the hospice interdimensional care process (assessment, care planning, goal setting, interventions, and evaluation) must involve three critical questions:

Are we approaching care based on the patient's and family's experience, values, goals, and choices?
How does an issue, problem, or opportunity in one dimension affect the other dimensions of the patient and family? How does an issue, problem, or opportunity affect the patient’s or family’s quality of life and relationship closure?

The main steps of the hospice interdimensional care process are similar to the nursing process but with a focus on preventing and managing suffering and on quality of life and relationship closure rather than rehabilitation or cure. Nurses must also look beyond problem identification as they apply the interdimensional care process and anticipate changes to prevent suffering while preserving opportunity for growth. At each step of the care process (assessment, planning, intervention, and evaluation), the three critical thinking questions must be applied.

Integrating the Nursing Process with the Hospice Interdimensional Care Process

Incorporating the nursing process into an interdimensional care process further defines the specialty of hospice nursing in that it involves the nurse working as a collaborative member of the IDT and expands the picture of the nursing process to an interdisciplinary interdimensional care process. All disciplines on the hospice team are valued, and their expertise is combined to apply the hospice interdimensional care process. The steps of the hospice interdimensional care process are outlined in the following paragraphs.

Step 1: Performing Interdimensional Assessment

Assessment begins with discussion soliciting information about the patient’s and family’s situation, including the values, wishes, and dreams that they identify as important. Data collection assesses all dimensions of a person and family as well as how changes in those dimensions affect the quality of life closure. Traditional nursing physical assessment is accomplished during this step, using norms for end-stage disease and symptom management.

Subjective and objective data are collected from a palliative, comfort care perspective and based on what patients and families define as important to them at this time. Their identified goals become the focus and driving force for the hospice team.

The focus of a palliative care assessment is to ask the question, “What is happening that is helping or hindering this patient and family from reaching their end-of-life goals?” From that perspective, the IDT supports integrated family systems theory, supporting the strengths of the patient and family while providing options for resources in areas of challenge.

Step 2: Identifying Specific Issues, Problems, and Opportunities and Their Causes

The next step involves identifying specific issues, which is comparable to developing the nursing diagnosis. A specific issue, problem, or opportunity is defined from a palliative perspective, and the cause is identified. In this step, hospice differentiates between definitions of problems that are expected norms for the dying process and those that are unexpected or may cause secondary suffering for the patient or family.

For example, a patient may become incontinent as her or his systems fail and death is imminent. This is an expected physical change during the dying process. Assessment of this using an interdimensional approach might determine that the problem is the potential for skin breakdown (with the cause being incontinence), rather than incontinence as the primary problem secondary to advanced disease. Another problem or issue may be that the “spouse is exhausted from being awake all day and night changing the patient’s linens secondary to incontinence of the patient.” What a nurse may instinctively identify as a problem in a curative model often becomes the cause of a problem in end-of-life care.

Another important difference in hospice nursing is that problems, issues, or opportunities are assessed and identified beyond the physical and functional dimensions, including the following for both patient and family:

- Physical symptoms and prevention of related suffering
- Psychosocial symptoms and prevention of related suffering
- Spiritual symptoms and prevention of related suffering
- Accomplishment of developmental tasks of life and relationship completion and closure to the extent that the patient and family choose to participate
- Issues and opportunities in the family dynamics and relationships
- Issues of grief, loss, and bereavement
- Functional status and environmental status

This step also involves determining the cause of the problem, issue, or opportunity. The cause of a medical problem can often be identified through physiological changes, but nurses must also take into consideration other causes related to all of the dimensions. For example, a patient with end-stage chronic obstructive pulmonary disease (COPD) may complain of shortness of breath. Initial reactions would be to identify the problem as shortness of breath “secondary to ineffective air exchange in the lung.” Again, in end-stage COPD, this is an expected norm. With further interdimensional assessment, the patient identifies episodes of shortness of breath secondary to “anticipated fear of being alone at night.” Obviously, the interventions are different if the full dimensions are assessed and the patient’s and family’s experiences direct the process.

The cause of a problem that is not physiologically based can often be attributed to the patient’s or family’s adaptation to the current situation or unfinished personal conflict. In this step, opportunities can also be identified for prevention of problems or issues, or situations can be presented that would enhance personal growth and completion of life and relationship closure tasks.

For example, a patient with COPD who was imminently dying was becoming progressively anxious, with increased episodes of shortness of breath despite all medical interventions. On assessment of this problem, the patient shared that...
he had a son to whom he had not spoken in more than 20 years. The patient was afraid of dying before mending that relationship, apologizing to his son, and letting him know he loved him. The hospice team assisted in locating his son and arranging for a visit. The patient and son were able to spend time together, give and receive forgiveness, and, in so doing, mend their relationship. The patient’s unfinished relationship issues and related anxieties were the cause of his physical episodes of shortness of breath. Hospice nursing involves a holistic approach that realizes the potential effect of one dimension (e.g., interpersonal) on all other dimensions and ensures that the nursing assessment gathers and uses all dimensional changes for optimal interventions.

Step 3: Planning Interdisciplinary Team Care

Interdisciplinary care planning is a process that occurs from the time the patient is referred through the family’s bereavement period. It occurs both in formal IDT care planning meetings and, between meetings, as patient and family needs change and members of the IDT collaborate on care. Patients and families are assessed by the nurse and by a psychosocial professional on admission. As the care plan is developed, each discipline blends its own area of expertise with those of other team members to formulate shared interventions that support the patient’s and family’s goals.

Similar to the nursing process, this step involves planning the care, including identifying patient and family goals and the appropriate staff and facilities; determining the best interventions; and devising a team plan for providing services. The key components in this process are collaboration, patient/family-directed goal setting, and IDT planning of interventions.

Collaboration. Collaboration builds an interdisciplinary awareness of interdependence with a common mission, values, and patient/family goals for optimal care. Collaboration is essential for all hospice professionals as they stimulate each other and innovative ideas and interventions are formulated. One of the key reasons for IDT collaboration is to share assessment data and feedback that each member was able to solicit from the patient and family so that a comprehensive interdisciplinary care plan can be established and mutually understood by all team members caring for that patient and family. The hospice nurse therefore collaborates first with the patient and family to determine their goals, and then with other IDT members to ensure a holistic approach to continuity of care. If the patient is residing in a facility, the nurse must also include the staff of that facility in care planning. Collaboration ensures continuity of care.

Patient/Family-Directed Goal Setting. A comprehensive plan is developed according to three types of goals: (1) patient/family goals, (2) life and relationship-closure goals, and (3) clinical obligation goals.

Primarily, the care plan should be directed by what the patient and family have defined as their goals. The hospice plan of care belongs to the patient and family; therefore, goals should be articulated from their perspective, not the nurse’s perspective of how things “should happen.” Goals articulated by hospice patients and families may include such things as being able to care for a spouse while he or she is bedridden or ranking pain as 2 or less out of 10 at meal times so that the patient can join the family at the table. Articulating goals from the perspective of the patient and family makes it apparent what direction each member of the IDT should take to collaboratively help them meet their goals. It also becomes apparent that the IDT as a group, not one discipline alone, is equipped to deal with complex issues associated with dying and bereavement.

Life and relationship completion and closure goals relate to the end-of-life accomplishments, the completion of unfinished business, landmarks and tasks of dying, the emotional and spiritual separation between family and patient, and anticipated changes for the caregiver after the death. Hospice nurses, as part of the IDT, add their expertise to support the patient and family in accomplishing life and relationship closure goals through disease and symptom management as well as emotional and spiritual support. An example of a life-closure goal as defined by the patient may be to take one last trip to visit and say good-bye to family and friends. The nurse may be involved by teaching energy conservation, the use of portable oxygen, transfer techniques for car transportation, or titration of medications to ensure comfort. Life and relationship-closure goals may also include “creating a memory book for my grandchildren to have when I’m gone” or being forgiven by a spouse for a life transgression. Again, the focus becomes the patient’s and family’s goals as they relate to life and relationship-closure tasks; the nurse collaborates with other team members, such as the psychosocial counselor or chaplain, to help the patient and family accomplish these goals.

Clinical obligation goals are identified by the IDT only in those situations in which the patient or family is unable to identify the problem or issue. These goals are strictly related to clinical obligation situations such as neglect or suicide, in which the team must establish goals to ensure the patient’s or family’s safety.

Interdisciplinary Team Planning of Interventions. Interventions are based on interdimensional assessment, with the overall goals of reducing or preventing suffering and accomplishing life and relationship closure in a way that is important and meaningful to the patient and family. Directed by the goals of the patient and family, and with their input and approval, the hospice nurse and the other IDT members collaborate to determine the optimal interventions that would move the patient and family closer to their goals.

The interdisciplinary planning process involves determining which discipline, or combination of disciplines, is most appropriate to assist patients and families in accomplishing their goals. Some patients and families may allow only one or two disciplines to be involved in their care. Some individuals expect nurses to provide care and are not always open to visits from social workers or chaplains. The nurse in these situations may
be the sole team representative, incorporating the expertise of all disciplines. If this happens, it becomes crucial that members of the IDT collaborate and share expertise so that interdisciplinary care can still be delivered and the patient’s and family’s goals can still be addressed. The nurse’s role may then include facilitating the involvement of the team to the degree that the patient and family are comfortable.

Step 4: Providing Interventions to Meet Patient and Family Goals

The hospice care plan involves interventions in four areas: palliative therapeutic interventions, educational interventions, collaboration interventions, and assessment interventions.

**Palliative Therapeutic Interventions.** Palliative therapeutic interventions include those that have been identified to be conducive to meeting the patient’s and family’s goals. These include both pharmacological and nonpharmacological interventions to best address the interdimensional adaptation and goals of the patient and family.

Hospice nurses must always be aware of not only the traditional medical interventions but also those interventions specific to the specialty of end-of-life care that support quality of life and relationship closure. An example is a patient who had a stroke that left him aphasic of both spoken and written word. During his lifetime, he had kept a scrapbook of national newspaper articles, including articles and current events journals. In the scrapbook, he had written his perceptions of how an event may have been significant to his daughter’s life. To assist this patient in finding meaning and purpose in his life, the nurse requested a volunteer to help the patient engage in life review. The volunteer visited the patient, reading the articles and the patient’s philosophical messages to his daughter related to each event in the history of their life together. Through the reading of these scrapbooks, the patient was able to sense his contribution and value as a parent.

Again, hospice nursing is based on a holistic approach and the understanding that life closure is an interdimensional experience for both the patient and the family.

**Educational Interventions.** As with all nursing practice, patient and family education is a cornerstone of hospice nursing. Because most patients followed by hospice do stay in their homes until death, the primary role of the hospice team is to empower the patient and family caregivers so that they can develop the skills to comfortably provide care and find meaning and purpose in the experience.

The nurse becomes involved in education of the patient and family as it relates to personal care, prevention of problems such as skin breakdown, administration and management of medications, nonpharmacological interventions such as therapeutic touch, application of heat, breathing exercises, and functional assistance with ADLs. As the patient’s disease progresses, the hospice nurse is also involved in educating the family about expected changes. Common responses to each stage of the disease and related interventions to decrease suffering are taught so that the patient and family are optimally prepared before the changes occur. When patients and families know what to expect, hospice can help to prevent or reduce anxiety related to the unknown. Critical to the specialty of hospice nursing is the ability to be comfortable having conversations with patients and families about the aspects of life and relationship closure, offering opportunities for them to identify what is most important and finding ways to support their goals in these aspects.

Another crucial goal of education is to provide information and support so that patients and families can advocate for themselves in all care settings, with other providers, and with other family members.

**Collaboration Interventions.** Crucial to ensuring unified delivery of care to patients and families is the practice of collaboration. In planning interventions, it is crucial to ensure that the patient, the family, and the professional caregivers are all involved. Caregivers include IDT members, facility staff, attending and consulting physicians, therapists, and the family. For example, the hospice nurse collaborates with the attending physician about the need for medication for symptom management or with facility nurses to educate and ensure around-the-clock administration of pain medications. If a hospice patient is residing in a nursing facility, the hospice nurse must collaborate with the nursing facility staff, communicating and documenting the outcome of that collaboration. Communication of these interventions is paramount to ensure continuity of care among team members, caregivers, and care settings.

**Assessment Interventions.** The final type of hospice nursing intervention is ongoing assessment necessary to determine whether continuation of the care plan is effective or optimal. For hospice nursing, this may include closely monitored titration of opioids for pain control or respiratory status to determine effective doses as symptoms change or the patient’s needs change throughout the trajectory of illness.

Step 5: Evaluating Interventions and Continuation or Revision of the Care Plan

With the patient and family as the core of the hospice team, evaluation begins with their perspective of the effectiveness of the care plan interventions in meeting their end-of-life and relationship closure goals. Do the interventions help them to reach their goals? What has been most beneficial from their perspective? What do they want to continue or discontinue? As with all other steps in the care process, the patient and family direct the care. Therefore, it is crucial that the hospice nurse involve the patient and family in evaluating the effectiveness of the care plan interventions on an ongoing basis.

By evaluating and documenting the effects of interventions, the hospice nurse shares his or her expertise as a valued member of the IDT. If the current care plan is effective at
meeting the patient’s and family’s palliative care goals, then interventions continue. If interventions do not meet the patient’s and family’s goals, then the hospice nurse collaborates with the patient, family, and IDT for additional assessment and identification of meaningful goals.

Illness, caregiving, dying, death, and bereavement are experienced in unique, personal ways. Hospice care allows for the patient and family to direct the care based on their own values, goals, and needs. A significant difference between traditional nursing and hospice care is the involvement of the patient and the family as they guide the hospice IDT in providing palliative care and services that are most meaningful to them.

"The glue that holds together this hospice approach to care is the interdisciplinary team."7 The primary purpose of the IDT model of care management is to build a caring community between the patient, the family, and the hospice team. This integrated community is responsible for responding to the patient’s and family’s dynamic needs 24 hours a day, 7 days a week. The entire IDT is accountable for the physical, psychosocial, spiritual, and bereavement needs of both the patient and the family, ensuring that the palliative care plan is carried out across all care settings.

Because the physical, psychosocial, spiritual, and bereavement needs of patients and families are inseparable, the interdisciplinary approach is also the hospice approach to care. The team, not just the hospice nurse, becomes the care manager. The patient, family, and IDT are equally important in problem solving and goal formulation, collaborating with each other for expertise and input into care planning. The hospice approach is a holistic care process that is directed by the patient and family to meet their interdimensional needs.

Care management by the IDT is a process, not an event. This process begins at the time the patient is admitted to the hospice program and continues until well after the death of the patient, through bereavement services for the survivors. Effective IDT care management promotes daily, ongoing collaborative practice that incorporates shared goals, care planning, role blending, and shared leadership.

Interdimensional Care Delivered by an Interdisciplinary Team

Chronic illness, aging, and terminal illness affect patients and families not only physically but psychologically, emotionally, spiritually, and financially. To provide effective, quality hospice care, all of these dimensions of the dying experience should be addressed. An IDT, incorporating the expertise of members from several disciplines who are trained to meet these varied needs of patients and families, provides the most effective holistic approach to end-of-life care.

In a traditional multidisciplinary approach to patient care, a member representing each discipline visits the patient and formulates goals depending on his or her own area of expertise. The patient and family may not always be considered together as a unit of care, and the specific goals of one discipline are not always shared by the other disciplines caring for the patient. Often, one discipline is the “case manager,” having more direction and input than the others in the care-planning process. This lack of collaborative care planning and goal setting can create an inconsistent approach that lacks cohesion and continuity and often frustrates those receiving care. The focus is on the “discipline” (e.g., nurse, social worker) rather than the patient and family. In the interdisciplinary approach to care, the nurse coordinates the plan of care with the patient, family, and other members of the IDT to “effectively mobilize each other’s skills to meet patients’ needs in a variety of healthcare settings.”30

The hospice IDT model improves on the multidisciplinary approach with a process that allows for the following:

- Patient and family direction of care and services and involvement in decision-making in all aspects of care
- Determination of patient/family value-directed care plan goals
- Collaboration of expertise from varied disciplines to meet patient/family goals
- Identification of interventions that support patient/family goals
- Role blending of expertise among disciplines toward common patient/family goals and outcomes

The IDT model provides optimal interdimensional care by jointly assessing and determining goals and sharing ideas for interventions with the patient, the family, and all team members working toward common goals and interventions. The success of the hospice IDT model lies in the partnership between patient/family and care professionals that best reflects the full scope and experience of illness, caregiving, dying, and bereavement—focusing on the choices, goals, wishes, and experiences of the patient and family.

The Hospice Interdisciplinary Team Structure and Role Blending

The structure of the hospice IDT is designed to meet the interdimensional needs of patients and families. To be most effective, care teams must be designed to honor the experience of the patients and families they serve. End-of-life care teams, the disciplines that comprise the IDT, and how they function as a collaborative team mirror the patient’s and family’s complex experience of life-limiting illness, caregiving, dying, death, and bereavement. Collaboration as an IDT focuses on transforming the patient’s and family’s end-of-life experience. The critical components of this interdisciplinary model can and should be offered in all settings of care for patients and families near the end of life.”31
As previously discussed, a number of dimensions define the full experience of patients and families. The related dimensions and the corresponding staff that form an effective hospice/palliative care team include the following:

- **Physical dimension:** physician, nurse, pharmacist, therapists, nutritionist, and volunteers
- **Functional dimension:** nurse, nursing assistant, therapists, and volunteers
- **Interpersonal dimension:** counselors, social worker, psychologist, and volunteers
- **Well-being dimension:** counselors, social worker, psychologist, chaplain, and volunteers
- **Transcendent dimension:** chaplain, counselors, social worker, psychologist, and volunteers

Interdimensional care provided by an IDT focuses on the experience of those served and the core disciplines that can best support that experience. By changing from a singular discipline to an interdimensional approach, all disciplines attend to all dimensions of the patient’s and family’s experience.

Whereas each discipline of the IDT involves special areas of expertise, responsibilities, and duties, the IDT approach to care management requires that each team member expand and blend the traditional roles with those of other disciplines to provide a holistic approach to patient and family care.

One must be an expert in her or his own discipline and have the basic competence to provide physical, psychosocial, spiritual, and bereavement care. Assessment, planning, intervention, and evaluation are ongoing responsibilities of all team members, implying that each is attentive to all dimensions of patient and family care. Role blending is essential for providing coordinated, comprehensive hospice services. As such, roles need to be dynamic, changing, growing, and overlapping.

**Direct Responsibilities of Patient/Family Care Team Members**

*Nurses, Including Advanced Registered Nurse Practitioners and Registered Nurses.* In the MHB model, the registered nurse is primarily responsible for physical care, including the patient’s physical condition and comfort, yet must also possess some level of expertise in psychosocial and spiritual aspects of care, to address the patient and family from a holistic perspective. She or he must be highly skilled in end-stage physical assessment, disease progression, and pain and symptom management. The nurse is also responsible for educating the patient and family regarding physical care, which includes such things as medication administration, equipment use, skin care, nutrition, catheter care, and transfers.

For those hospice programs that are MHB certified, regulations require the coordination of care by a registered nurse and primary physician. As a member of the IDT, the nurse’s expertise related to disease and symptom management is one of the critical aspects of providing competent end-of-life care. The nurse’s primary role involves managing and preventing the physical and functional decline, to reduce suffering so that the patient and family can attend to activities that promote quality of life and relationship closure.

The hospice nurse is also responsible for supervising related nursing personnel, including licensed practical nurses, certified nursing assistants, and home health aides. Communicating care plan goals and interventions and monitoring and evaluating the care provided by these other IDT members are the responsibilities of the hospice registered nurse.

Advanced registered nurse practitioners are most often used as collaborative primary care practitioners, providing palliative care consultation and care management for the expanded hospice palliative care programs (e.g., pain consultation in hospital and long-term care settings). Advanced registered nurse practitioners and clinical nurse specialists are also involved as consultants to the primary hospice team.

**Psychosocial Professionals.** Psychosocial professionals may include social workers and counselors who are competent in psychosocial assessment, family dynamics, social/emotional therapeutic interventions, grief and bereavement, and group work. They provide support to patients and families, assisting with psychological issues, emotional responses, and the overall adaptation of the patient, family, and significant others through counseling and utilization of community resources. They may also be involved with legal issues, advance directives, and funeral arrangements. Overall, the psychosocial professional helps the patient and family as they adapt to and cope with a terminal illness and the survivors as they adjust to life during the bereavement process. It is also crucial for nurses to possess expertise in end-of-life psychosocial issues because they, too, will be involved in addressing and supporting the patient’s and family’s psychosocial needs as members of the IDT. Both the psychosocial and the spiritual care team members are experts in addressing many of the aspects of care relating to life and relationship closure.

**Spiritual Care Professionals.** Spiritual care is a significant component in end-of-life care. The spiritual caregiver, also known as the chaplain, clergy person, or pastoral care worker, can be a paid hospice professional or a resource volunteer from the community. Hospice spiritual care is nonsectarian, nondenominational, and all-inclusive, with the goal of supporting the patient’s and family’s spiritual and/or religious practices. The hospice philosophy in terms of spiritual care is nonjudgmental and focuses on healing, forgiveness, and acceptance. Spiritual care is provided through direct spiritual counseling and support by collaboration with the patient’s and family’s own clergy or by working with patients who do not have a clergy person but request spiritual care. Spiritual interventions can include prayer, rites, rituals, assistance in planning and performing funerals and memorial services, and assistance with ethical dilemmas. Again, the nurse must have

---

**General Principles**
some level of expertise in the spiritual aspects of care to address the patient’s and family’s spiritual needs.

**Patient’s Primary Physician.** The patient’s primary physician is also part of the IDT. The primary physician is responsible for overseeing patient care. The physician often refers the patient to hospice; certifies the patient’s terminal condition; and collaborates throughout the care process, providing the admitting diagnosis and prognosis, current medical findings, dietary orders, and orders for medications, treatments, and symptom management.

**Hospice Medical Director.** The hospice medical director is a member of the IDT. She or he is responsible for the overall medical management of all patients. Depending on the structure of the hospice program, the medical director may also become a patient’s primary physician. The role of the hospice medical director is to participate in the team care planning process as a collaborative member of the IDT. The director may also be responsible for the oversight of medical services provided by the hospice.

**Certified Nursing Assistant or Home Health Aide.** Certified nursing assistants provide basic physical and functional care if there is a need, as well as patient and family support. They provide and educate caregivers on personal care assistance with ADLs, which may include bathing, grooming, mouth care, skin care, transfers, and repositioning, and sometimes with light housekeeping, shopping, cooking, and laundry. Visits vary depending on patient and family needs and what is most important to the patient at each visit. At times, a walk in the garden is more therapeutic than a bath.

**Homemaker/Companion.** The homemaker/companion assists the patient and family by doing light housekeeping, meal planning and preparation, laundry, and shopping and by acting as a companion to the patient. The homemaker/companion does not provide direct, hands-on care. For elderly patients living alone, it is often the addition of a homemaker/companion that allows them to remain independent in their homes until they die.

**Patient Care Volunteer.** Volunteers play an integral role in providing hospice care and are fundamental to the hospice philosophy. Hospice patient care volunteers are trained to work in a variety of roles. The most common role is working with a single patient and family in providing support through companionship, listening, diversion, delivering medications, running errands, taking patients to appointments or on outings, shopping, or preparing a special meal. They may provide companionship to patients in extended care facilities or respite time for the home patient’s caregiver. Specialized volunteer roles may include bereavement volunteers, who work exclusively with grieving families and friends, or those who sit at the bedside during the dying process. The scope of volunteers’ duties is all-inclusive, depending on the needs of the patient and family and their quality-of-life goals.

**Roles and Responsibilities of Consultative Team Members**

Consultative team members participate in direct patient care as needed to meet the palliative care goals of the care plan. Consultative team members may include the hospice team medical director; consulting physician; psychologist or psychiatrist; nutritional counselor; community clergy; clinical pharmacist; occupational, physical, respiratory, speech, and language therapists; intravenous infusion nurse; and members of pharmacy, radiology, laboratory, and durable medical equipment services.

**Coping with Cumulative Loss:**

**The Nurse as Caregiver**

The hospice philosophy of care, which emphasizes intense interpersonal care and active involvement with the patient and family, creates more intense and more intimate relationships among the nurse, patient, and family than exist in traditional health care settings. Like families who grieve the loss of their loved ones, the hospice nurse also grieves the loss and, in fact, may need to grieve on a continuous basis due to the number of deaths that occur. As the hospice nurse adjusts to caring for dying patients and their families, the stress of coping with death on a daily basis can trigger many emotional feelings, reactions, and behaviors.

Other factors may also influence a nurse’s successful adaptation to caring for dying patients and their families. If the nurse has experienced death on a personal level or has experienced life changes that signify loss (e.g., children leaving home, divorce), caring for dying patients and families may trigger issues of unresolved grief. The nurse’s ability to verbalize his or her feelings regarding death and loss with other members of the IDT is important for support and for normalizing these feelings.

Hospice nurses who are unable to process these losses through appropriate grief and personal death awareness may begin to distance themselves from emotional involvement with patients and families. This withdrawal may negatively affect not only the coping ability of the professional but also the quality of compassionate delivery of care and the ability to meet the needs of dying patients and their families during the terminal phases of an illness.

**Stages of Adaptation for the Hospice Nurse**

Hospice nurses go through many stages when they begin caring for dying patients and their families. Successful progression through these stages and the support systems in place to facilitate successful progression are vitally important in determining whether the nurse will be comfortable and effective in caring for the dying.

As proposed by Bernice Harper, an expert in anxiety issues in the professional caregiver, there are six stages of adaptation...
that characterize the hospice nurse’s normal progression, adaptation, and coping in caring for the dying: intellectualization, emotional survival, depression, emotional arrival, deep compassion, and The Doer. Five of these stages and the emotions, behaviors, and reactions of each stage are shown in Figure 2–1 and Table 2–7.

**Intellectualization.** Intellectualization usually occurs during the first 1 to 3 months of caring for the dying. During this time, professional caregivers are usually confronted with their first experience of a hospice death. Nurses in this initial stage spend much of their energy learning the facts, tasks, policies, and procedures of the job. Emotional involvement in the dying and death of the patient may be inadvertently avoided, and the hospice nurse seldom reacts on an emotional level to the death.

**Emotional Survival.** Emotional survival generally occurs within 3 to 6 months of employment. Emotional involvement and a deeper connection with the patient and family occur. The nurse begins to confront the reality of the patient’s death, to face her or his own mortality, and to feel sadness about the patient’s situation and/or the loss of the patient. Often during this stage, the nurses begin to fully understand the magnitude of their roles and responsibilities and to question their abilities and desire to continue caring for dying patients and their families. This is a crucial time, and the nurse needs to be reassured and given support and resources to feel competent and confident so that he or she can progress successfully in the field.

**Depression.** Depression occurring at 6 to 9 months is often a time when hospice nurses process the losses rather than avoid them or remain emotionally detached. They begin to explore their own feelings about death, accept their own mortality, and accept death as a natural part of life.

It is in this stage that hospice professionals positively move toward resolution of death and loss and accept the reality of death and dying, or negatively resolve death and loss by choosing to avoid the emotional pain. In positive resolution, hospice professionals emotionally arrive at a comfortable place in caring for dying patients and their families.

**Emotional Arrival.** Emotional arrival occurs within 9 to 12 months of caring for the dying. With positive resolution of the last stage, hospice professionals become sensitive to the emotional needs and issues associated with dying and death. They can now cope with and accept loss, participate in healthy grieving, experience and conceptually work within the principles of hospice philosophy by advocating for the patient and family, and become involved with patients and families on a deeper level.

**Deep Compassion.** Deep compassion occurs after the first year as a hospice nurse. In this stage, hospice professionals begin to refine their knowledge and skills and are comfortable in providing compassionate, physical, psychosocial, and spiritual care to dying patients and their families. This stage is characterized by personal and professional growth and development.

**The Doer.** The final stage, the doer, is the culmination of nurses’ experiencing the first five stages in a healthy and balanced manner; this outcome is characterized by hospice professionals who are efficient, vigorous, knowledgeable, and able to understand and comprehend humankind. Death has an inner meaning embedded in caring. Doers have grown and developed personally and professionally through the experiences of caring for the terminally ill.

**Support Systems**

In caring for dying patients and their families, the hospice nurse is vulnerable to emotions, reactions, and behaviors that can ultimately affect his or her personal well-being and the delivery of quality palliative care. To effectively care for patients and families, the nurse must also be responsible for attending to her or his own emotional, physical, and spiritual needs. Successfully coping with and adapting to dying, death, and cumulative loss is possible only if a system is in place that provides support to the nurse. Support systems may include personal death awareness exercises, time to verbalize in one-on-one counseling or with the IDT or both, supervisor support, preceptors or mentors, spiritual support, funeral or memorial services for closure, joint visits with members of other disciplines, and educational opportunities. The nurse should also explore individually facilitated support systems through journal writing, exercise, relaxation, meditation, and socialization with family and friends. By exploring and accessing support systems, hospice nurses can find satisfaction, fulfillment, and growth and development in their personal and professional lives as they provide compassionate end-of-life care to patients and their families.
In the national dialogue about improving care at the end of life, access to hospice services has been raised as a public policy and public health concern. There is acknowledgment of the value of hospice care for patients who need palliative care, with the recognition that there are barriers to its full utilization. Often patients are referred for hospice care just a few days or even hours before their deaths. Hospice demonstration projects are now underway testing how to care for patients who have an extended life expectancy or are receiving experimental or disease-modifying treatments. Policy proposals have been offered to allow for hospice programs to receive reimbursement

for providing palliative care consultations to recently diagnosed
patients and how to define alternative eligibility criteria that
could be substituted for the 6-month prognosis requirement.33
Many factors contribute to late referrals and access barriers, and
communities are collaborating to ensure that palliative care is
available across settings throughout the disease trajectory.12

A Death-Defying Society

The prevailing attitude of society toward death continues to be
“death-defying.” Unquestionable acceptance of innovation, effi-
ciency, science, technological advances, and the ability to prolong
life reflects the current perspective on health care. Therefore, ac-
ceptance of death as a natural process is difficult and offensive.
Even with the growing hospice movement, most deaths happen
in hospitals, often with uncontrolled pain.34 As experts in the care
of patients and families at the end of life, hospice workers will
continue to shape the way in which people view dying and death.

Access Barriers

As a result of dissatisfaction with care afforded the dying more
than 25 years ago, community members introduced the vision
of hospice care. Congress adopted this vision through the cre-
aton of the MHB in 1982. Millions of Americans have bene-
fited from care under this act, but it has fallen short of meeting
current needs of the dying.

At the request of the NHPCO, the Committee on the
Medicare Hospice Benefit and End-of-Life Care spent almost a
year addressing issues related to hospice and end-of-life care.
As part of the committee’s review and recommendations, bar-
rriers to achieving the characteristics of the ideal future hospice
and extending hospice to more Americans were identified. The
specific recommendations of the report were wide-ranging,
from improving the MHB to changing the education of health
and human service professionals to raising the expectations for
performance by hospice programs. All are important, but the
following steps were identified as having the highest priority:

• Eliminating the 6-month prognosis under the MHB
  and identifying alternative eligibility specifications;
• Collecting and analyzing comprehensive data on the
cost of meeting patient and family needs through
hospice, with the intent to address inadequacies in
Medicare payments;
• Developing outcome measures for assessing the
quality of end-of-life care;
• Engaging the public in a campaign to create wider
understanding and utilization of hospice care.35

Prognostic Limitations

One of the significant factors limiting access to hospice care
is the determination of when hospice care should begin. There
is mounting clinical evidence of the appropriateness
of palliative care but few documented, valid, and reliable
prognostic indicators of when palliative care should begin,
especially for patients with diagnoses of chronic noncancer
disease or aging and multisystem failure. This ambiguity
can cause delay in referral to hospice or toward any palliative
care focus. Further development and research on practice
protocols for the care of patients with terminal disease is
needed.

Terminally ill persons, given physician-certified prognosis
of 6 months or less to live, represent patients who are poten-
tially eligible for the MHB model. From historical,36 contem-
porary,37 and scientific perspectives,38 however, determination
of terminal status is notoriously elusive.

In an effort to implement criteria to identify when hospice
should begin, the Centers for Medicare and Medicaid (for-
ermerly the Health Care Financing Administration) imple-
mented Medicare prognostic criteria called Local Medical
Review Policies (LMRPs) through the national Fiscal Inter-
mediaries in the mid-1990s. The appropriateness of the
Medicare prognostic criteria (LMRPs) has been contested on
several points. First, mounting quantitative evidence shows
little association between the LMRPs and short-term sur-
vival outcomes in hospice.39,40 Second, although Medicare
hospice was founded on the value of holistic, physical, psy-
chosocial, and spiritual treatment of dying individuals, the
LMRP criteria exclude nonphysical markers of disease pro-
gression. Third, although the consequences of regulatory
reform have yet to be fully understood, the LMRPs appear to
disadvantage those who are less obviously and imminently
terminally ill. Sets of criteria to reliably distinguish termi-
inally individuals (i.e., those with 6 months or less of life
expectancy) from persons with severe and progressive dis-
ease would serve important clinical, practical, and humani-
tarian goals in hospice and in many other health care
settings.44 However, the LMRP criteria appear to have limited
scientific merit.41

As is apparent from the findings of the largest project testing
the validity of the LMRPs as prognostic criteria, application of
the LMRP criteria can yield considerable misclassification.
Moore observed a consistent pattern of relatively low rates of
false-positive error and much higher corresponding rates of
false-negative error. The practical consequence of high false-
negative errors is erroneous classification of individuals who
would survive less than 6 months as ineligible for the MHB.
The consequence of false-positive errors is erroneous classifica-
tion of individuals who will survive longer than 6 months as
MHB-eligible. Relative to the costs and benefits of regulatory
innovation, false-negative errors most disadvantage patients,
families, and providers, whereas false-positive errors most dis-
advantage payers of public services.42 These results further sup-
port those of previous smaller studies, which also indicated
that prognostication is not a clear and concise science. The
MHB was initially implemented with the understanding that
the IDT in collaborative assessment would be the ideal way to
identify when someone is eligible for the MHB.
Eliminating Barriers and Improving Access

Hospice programs have begun to respond to these barriers and are now providing a broader range of services by using more liberal internal eligibility criteria, flexible state hospice licensing provisions, home health agency licensure, no-fee volunteer support programs, counseling centers, and other approaches. Many hospice programs have extended their services to incorporate new palliative treatments, eliminated access barriers by admitting patients who live alone or lack a family caregiver or stable home setting, and cared for more patients with diagnoses other than cancer, including children with life-threatening illnesses. Other hospice agencies have pursued a somewhat different path to the same goal of expanded access by labeling their broader service offerings as “palliative care.” Some have changed their services and their names to include palliative care components through discrete programs or separately incorporated subsidiaries, integrating those initiatives with traditional hospice care.32

The Comprehensive Hospice Center model, described earlier, aligns care and services with the needs of an aging population; these centers are compatible with a public health paradigm reflecting the preventive and care needs of youth, middle-aged, and older persons—a birth-to-death public health paradigm (Figure 2–2). Comprehensive hospices provide primary prevention services to the community by offering education on terminal disease trajectories and end-of-life care and caregiving and by providing bereavement support to communities. Through such activities, these hospices have the potential to contribute to the occurrence of lower survivor morbidity and mortality—to contribute to the public’s health.12

Comprehensive hospices provide educational programs and services in schools and universities, in workplaces, and in other public places within communities (e.g., churches); they sponsor culturally diverse initiatives and help in the creation and dissemination of new knowledge.

Hospice–Hospital Collaborations

A growing number of people in acute care settings are recognized as being in need of palliative care. It is now recognized that palliative care should not be an alternative to curative or life-prolonging treatment but should be offered in conjunction with such medical treatment. It is also recognized that this type of care is increasingly important as the health care system faces the need to find ways to treat the growing number of older adults with complex chronic illness.\(^\text{33}\)

One approach to meeting the expanding needs of patients and families is evident in the growing number of partnerships between hospital systems and hospice programs. A study conducted by the NHPCO and the Center to Improve Palliative Care identified various structures currently in place to meet the palliative care needs of patients in acute care. Their report, Hospice–Hospital Collaborations: Providing Palliative Care Across the Continuum of Services, offers glimpses of how some models of collaboration are contributing to the expansion of palliative care in the hospital setting. Hospital–hospice collaboration is generally proceeding on two tracks. The first overall direction lies in enhanced use of the MHB for appropriate patients by promoting closer relationships between hospice programs and hospitals, offering education, developing specialized units, and encouraging the direct admission of hospitalized patients to hospice. The second track involves development of new, nonhospice benefit services, such as hospice palliative care management and consultation services.\(^\text{13}\)

When Nurses Should Consider Hospice for Their Patients

All nurses must be familiar with the benefits and services of their local hospice programs, so that they can effectively educate and advocate for palliative care when their patients and families could benefit from this approach and scope of supportive services. Considering the expanding hospice models, there are many myths and misperceptions that must be eliminated—such as the need to be within 6 months of death to receive hospice services—so that patients and families can be optimally supported. The most common comment nationally on hospice family satisfaction surveys is, “I wish we had hospice sooner.” The voices of these families support the need for earlier referral to hospice. It is important for nurses providing end-of-life care to consider when to think about hospice. Table 2–8 lists practical scenarios to guide nurses in offering hospice as a supportive service to patients and families throughout the lifespan. Hospice teams are expert at assessing palliative care needs and are available to assist nurses in determining which services may benefit a given patient. A call to collaborate with the local hospice provider can initiate this assessment.

The Funding of Hospice Programs

The original hospices, which began as grassroots community efforts, were funded almost exclusively by charitable support, grants, and volunteer efforts. Some components of care were supported by Medicare or insurance, such as skilled nursing visits, medications, or durable medical equipment on a per-unit fee-for-service basis allowed under an acute care model. In 1980, the U.S. Congress authorized a 2-year demonstration program in 27 hospices around the nation to study the outcomes of hospice care and the costs associated with it. The demonstrations included researchers at each site who collected both field data from patients and families and cost data from each organization. Ultimately, the demonstration was continued for an additional year. Based on very preliminary findings, Congress created the MHB as a 2-year endeavor and then subsequently approved it as a permanent part of the Medicare program in August of 1982.

The MHB was a landmark event under Medicare in that it was the first formal recognition of the unique needs of dying patients and their families. It was also the first form of what ultimately became managed care. It included provisions never before included as health care benefits, such as spiritual support, volunteers, and bereavement support for family members. It was an all-inclusive benefit in which all services related to the terminal illness were to be provided, coordinated, and paid for through the hospice program. Although this approach is now frequently viewed as a strategy to control costs, it was at the time designed in this manner because surviving family members cited the complexity of bills and the financial toll of a terminal illness as one of the greatest stressors.

The benefit included the following core hospice services: nursing care, medical and social services, physician services, counseling/pastoral services, short-term inpatient and respite care, medical appliances and supplies including drugs and biologicals, home health aide and homemaker services, therapies (physical, occupational, speech), bereavement counseling, and drugs for symptom management and pain control.\(^\text{15}\) It also had a provision for four levels of care depending on the intensity and place of care rendered on any given day. Continuity across all care settings with hospice professional management of care was and continues to be a strong underpinning of the benefit.

Following the MHB demonstration and benefit development, Medicaid and private insurance hospice benefits began to emerge. Ultimately, most states developed Medicaid benefits, which are mandated to be no less than the Medicare benefit. Private insurers frequently model their benefit on the MHB, although they are under no mandate to do so.

Most hospices are committed to providing care regardless of ability to pay, and they continue to be dependent on charitable dollars to provide such care. Additional supportive services, beyond the benefit, such as children’s programs, in-home caregiver programs, hospice residences, and community bereavement and education programs, are provided in many hospice communities.

</tbody>
</table>

*continued*
Although a small portion of all people receiving health care are at the end of life and receiving terminal care, the terminally ill consume a disproportionate percentage of all health care expenditures. There are several studies on the cost savings in hospice versus traditional health care at the end of life. Hospice has remained a positive example of integrating a managed care model with proven cost savings while meeting patients’ and families’ needs and receiving high quality scores.

Initially, hospices were slow to seek certification for Medicare status, but this connection has grown steadily as hospices have become more comfortable with assuming the risk of total costs of care. There were also financial reimbursement and other utilization caps in the program that concerned many. Today, most hospices are Medicare certified, and the number of recipients of hospice care in America has grown commensurately, from approximately 500,000 patients and families in 1998 to more than 885,000 in 2002.10

### The Medicare Hospice Benefit

The levels of care outlined in the MHB reflect the variations in care intensity that are required to meet patient and family needs in the last phase of life. Medicare provides coverage for hospice care to Medicare beneficiaries who have elected the hospice benefit and who have been certified as terminally ill with a prognosis for a life expectancy of 6 months or less. Once elected, Medicare pays one of four prospective, per diem rates for hospice care: routine home care, continuous home care, respite care, and general inpatient care. Each of these payment categories is defined later. Changing the level of care is determined through a collaborative effort by the hospice IDT, patient, family, and primary physician.

**Routine Home Care.** Routine home care is provided in the patient’s home, nursing home, or residential care setting or wherever the patient and family reside. The hospice core
services provided at this level include nursing care, home health aide care, social services, therapies, medical appliances and supplies, and drugs.

**Continuous Care.** Continuous care covers patients in brief periods of crisis, during which 8 or more hours per day of care is provided to the patient at home, with at least 50% of the care being delivered by a registered nurse or licensed practical nurse.

**Inpatient Respite Care.** Inpatient respite care covers patients in an approved inpatient facility for the relief of the patient’s primary caregiver, for a maximum of 5 days per episode. It includes coverage for ancillary services (e.g., oxygen, laboratory, pharmacy).15

**General Inpatient Care.** General inpatient care covers patients in a participating hospice inpatient unit of a hospital, skilled nursing facility, intermediate care facility, or free-standing hospice for medically necessary days for the control of pain or acute or chronic symptom management that cannot be managed in other settings. It includes coverage for ancillary services (e.g., oxygen, laboratory, pharmacy).15

**The Medicaid Hospice Benefit**

Medicaid coverage for hospice is patterned after the Medicare benefit, including both patient eligibility requirements and coverage for specific services. States do have some flexibility in developing their hospice benefit.

**Private Insurance Reimbursement and Managed Care**

Private insurance companies have begun to realize the benefits of hospice care and are including a hospice benefit in their services. As with Medicaid, many private insurers pattern their benefit after Medicare. Some insurers have negotiated services with hospices, including those palliative care consultation and care management services of the Community Hospice Model, before the MHB services begin. Many managed care companies have also reflected the Medicare benefit in services provided to their members either through their own hospice programs or under contract with programs serving the patient’s community.

**Conclusion**

Hospice is more than a program of health services. It is an approach and philosophy of care and services that strive to encompass and support the full experience of illness, aging, caregiving, dying, and bereavement for both the patient and the family. Although the last phase of life and relationship is a difficult time, with sensitive support it can be a time of tremendous growth and opportunity for the person who is dying and for loved ones—such as in the finding of meaning and purpose in one’s suffering, the value of one’s life accomplishments, the deepening of relationships, and the personal spiritual significance of the experience.

Nurses can positively affect this experience for others by allowing the patient’s and family’s personal values and goals to direct the support and care they offer as they are invited to share in this intimate time of life. Regardless of the site of care or type of program or services, nurses providing end-of-life care must be proficient in end-stage disease and symptom management. They also have a responsibility to be knowledgeable about the services a hospice program can offer their patients and families and to know when to consider offering hospice care. Nurses must be guided by dignity, compassion, love, and individual acceptance of patient and family values and choices to ensure quality end-of-life care.

**References**

An effective assessment is key to establishing an appropriate nursing care plan for the patient and family. The initial palliative care nursing assessment varies little from a standard nursing assessment. In order to assess effectively, members of the health care team need to maximize their listening skills and minimize quick judgments. Medical experts contend that during a medical assessment interview, in which a physician mostly listens and gently guides the patient’s story, the physician can accurately diagnose the patient’s problem 70% to 80% of the time.

The goals of the palliative care plan that evolve from the initial and ongoing nursing assessments focus on enhancing quality of life. Ferrell’s quality-of-life framework is used to organize the assessment. The four quality-of-life domains in this framework are physical, psychological, social, and spiritual well-being. For the purpose of this chapter, the psychological and social domains are combined into one, the psychosocial domain.

Because the needs of patients and families change throughout the course of a chronic illness, these quality-of-life assessments are examined at four times during the illness trajectory: at the time of diagnosis, during treatments, after treatments (long-term survival or terminal phase), and during active dying.

CASE STUDY
Ghedi, a Man with Colon Cancer

Ghedi, a fictitious patient from Somalia, serves as a case example throughout his illness experience with colon cancer. He is a 68-year-old man who emigrated to the United States in 1998. He lives with his older brother, Asad; his sister-in-law, Laila; and their adult son and daughter. Asad and his family have lived in the United States for 15 years; they have developed ease with English and are sensitive to many American customs and norms. Ghedi came to this country after losing his wife and son in the war in his native land in 1991. He has continued to
General Principles

48

Malignant versus Nonmalignant Terminal Diseases

Because the authors of this chapter work primarily with oncology patients, much of the assessment content is based on the cancer experience. The experiences of terminally ill patients with diseases other than cancer can be equally dynamic in terms of the continuous or episodic declines they face throughout the illness trajectory.

A primary difference between patients with malignant and nonmalignant illness lies in the current acceptance by the medical establishment that efforts toward cure are unavailable for many nonmalignant diseases. Thus, from the start, the focus of medical care for these patients is palliative rather than curative: reduction of symptoms, improvement of quality of life, and optimization of the highest level of wellness. Examples of these kinds of illness today include acquired immune deficiency syndrome (AIDS); refractory cardiovascular, hepatic, and renal diseases; brittle diabetes; and neurological disorders such as multiple sclerosis, cerebral palsy, amyotrophic lateral sclerosis, Parkinson’s disease, and Alzheimer’s disease. For some of these diseases, the focus of medical care may include attempting to extend life through research with the hope of finding a cure.

In contrast, medical professionals and the public are continually looking and hoping for a cure for cancer. As a result, the oncology patient may repeatedly alter his or her expectations about the future. Words describing the status of the disease during a cancer illness include “no evidence of disease,” “remission,” “partial remission,” “stable disease,” “recurrence,” “relapse,” and “metastasis.” Patients report experiencing a “roller-coaster ride,” in which the hopeful points in remission are often followed by a crisis with relapse or disease progression. Patients may be told, more than once, that they are likely to die within a short time. Then, they may recover and do well for awhile. As a result, the reality of death may be more difficult when it does occur.

Introduction to Physical Assessment

Before beginning the assessment interview and physical examination, it is important for the nurse to establish a relationship with the patient by doing the following:

• Introducing himself or herself to the patient and others in the room.
• Verifying that this is the correct patient.
• Determining how the patient would like to be addressed: first name? last name? a nickname?
• Explaining the purpose of the interaction and the approximate length of time that he or she intends to spend with the patient.
• Asking the patient’s permission to proceed with the assessment, giving the patient an opportunity to use the restroom, and excusing others whom the patient does not wish to be present during the interview and examination. (Some patients may want significant others to be present during the interview, to assist with recall, but not during the examination. The nurse needs to modify the assessment routine to accommodate the patient’s preferences.)
• Taking a seat near the patient, being respectful of the patient’s cultural norms for physical closeness and eye contact.
• Inviting the patient to tell about how he or she learned of the illness.
• Taking care not to interrupt the patient too often; using communication techniques such as probing, reflecting, clarifying, responding empathetically, and asking open-ended questions to encourage greater detail if the patient’s account is brief or sketchy.

Refer to Figure 3–1 for a sample physical symptom assessment charting form that includes a severity measurement scale.

Introduction to Psychosocial Assessment

Tables 3–1 through 3–3 provide a framework for three key elements of assessment: conducting a psychosocial assessment, distinguishing normal grief from depression, and doing a general mental status assessment. Throughout the illness trajectory, the nurse can use these tools to monitor the patient’s response to illness and treatment.

Anyone diagnosed with a serious or life-threatening illness experiences many losses. However, responses to illness vary tremendously among individuals. In addition, the same person may respond differently at various times during an illness. How a particular patient copes depends on the severity of the illness, the patient’s history of coping with stressful life events, and available supports. Some individuals develop coping styles that are more helpful than others when facing a life-threatening illness.

The nurse needs to assess two very important parameters in order to assist the patient in coping in the most functional way possible. These parameters are the patient’s need for information and her or his need for control in making decisions. Observers of “exceptional” patients, such as Bernie Siegel, have

Principles of Patient and Family Assessment

noted that patients who are proactive, assertive information-seekers often appear to have better outcomes than patients who are passive in making decisions. Indicators of a person’s need for control may include the following:

- Comfort in asking questions
- Willingness to assert own needs and wishes relative to the plan of care
- Initiative taken to research print and Internet resources on the illness and treatment

Table 3–1 provides details for doing a psychosocial assessment. More detailed information on the psychosocial aspects of oncology can be found in Holland’s *Psycho-oncology.*

Grief is a normal reaction to loss, especially a major loss such as one’s health. In chronic illness, grief is likely to be recurrent as losses accumulate. This does not make it pathological, but it does form the basis of the “roller-coaster” phenomenon that many patients describe. Some patients with advanced disease have been able to integrate their losses in a meaningful way, managing to reconcile and transcend them. An example of such a person is Morrie Schwartz, who wrote about his illness in *Letting Go: Morrie’s Reflections on Living While Dying.*

Table 3–2 contrasts and compares normal grief with depression, to assist the nurse in determining when a patient needs to be referred for counseling. For further information, consult John Schneider’s classic work, “Clinically Significant Differences between Grief, Pathological Grief and Depression.”

In some cases, patients may appear to be having difficulties in coping but the nurse cannot easily identify the specific

Introduction to Spiritual Assessment

Although Chapter 30 provides a more detailed discussion of spiritual assessment, the following discussion illustrates the importance of assessing the spiritual domain as a component of a comprehensive evaluation.

Attempts to define spirituality can often result in feelings of dismay and inadequacy. It is like trying to capture the wind or grasp water. Therefore, assessing and addressing the spiritual needs of patients can be a formidable challenge. Spirituality may include one’s religious identity, beliefs, and practices, but it involves much more. The person without an identified religious affiliation is no less spiritual. Indeed, the desire to speak one’s truth, explore the meaning of one’s life and illness, and maintain hope are fundamental human quests that reflect the depth of the spirit. Haase and colleagues8 concluded that the spiritual perspective is “an integrating and creative energy based on belief in, and feeling of interconnectedness with, a power greater than self.” Amenta9 viewed spirituality as “the life-force springing from within that pervades our entire being.” Hay10 defined it as “the capacity for transcending in order to love or be loved, to give meaning, and to cope.” Doyle11 wrote, “Spiritual beliefs may be expressed in religion and its hallowed practices, but a person can and often does have a spiritual dimension to his or her life that is totally unrelated to religion and not expressed or explored in religious practice.” He further noted that “a prerequisite to discussion of spiritual issues with a patient is to create a situation which permits speaking of spiritual problems, i.e. environment, ambiance, and attitude.”

</table>
The spiritual issues that arise after the diagnosis of a serious or life-threatening illness are abundant and varied. As a person progresses through the phases of an illness (diagnosis, treatment, posttreatment, and active dying), he or she is confronted with mortality, limitations, and loss. This frequently leads to questions such as, “What is my life’s purpose?” “What does all this mean?” “What is the point of my suffering?” “Why me?” and “Is there life after death?” Indeed, Victor Frankl,12 in his classic work, Man’s Search for Meaning, affirmed that the quest to find meaning is one of the most characteristically human endeavors. To find meaning in suffering enhances the human spirit and fosters survival.

According to Abraham Maslow’s13 theory, human needs can be placed on a hierarchy that prioritizes them from the most basic physical and survival needs to the more transcendent needs. Thus, a patient’s ability and willingness to engage in dialogue about issues of meaning, to discuss successes and regrets, and to express his or her core values may occur only after more fundamental needs are addressed. This reality in no way diminishes the spiritual compared with the physical; rather, it supports the need for an interdisciplinary approach that provides holistic care of the entire person. For example, if a physician relieves a young woman’s cancer pain and a social worker secures transportation for her to treatments, she and her family may be more able to address the vital concerns of her soul.

The sensitivity of the nurse to a patient’s spiritual concerns improves the quality of palliative care throughout the illness trajectory. When members of the health care team serve as “companions” to a patient and family during their journey with an illness, they offer vital and life-affirming care.

Responding to the spiritual needs of patients and families is not solely the domain of the chaplain, clergy, or other officially designated professionals. All members of the health care team share the responsibility of identifying and being sensitive to spiritual concerns.

It is vital that a patient be viewed not in isolation but in the context of those who are affected by the illness. Thus, the focus of spiritual assessment includes both the patient and the family or significant others. This perspective affirms the power of a systems view, which sees the patient and family as interdependent and connected. Providing support to family members not only assists them directly but may also contribute to the patient’s comfort secondarily, as she or he sees loved ones being cared for as well.

The purpose of a spiritual assessment is to increase the health care team’s knowledge of the patient’s and family’s sources of strength and areas of concern, in order to enhance their quality of life and the quality of care provided. The methods of assessment include direct questioning, acquiring inferred information, and observing. This is most effectively accomplished when a basis of trust has been established. Fitchett14 noted that spiritual assessments consist of both “substantive” and “functional” information. Table 3–4 examines these categories of spiritual assessment.

### Table 3–4

</tbody>
</table>

One of the fundamental principles underlying spiritual assessment and care is the commitment to the value of telling one’s story. Alcoholics’ Anonymous, a very successful program with spiritual tenets, acknowledges the power of story. This might be paraphrased as follows: in the hearing is the learning, but in the telling is the healing. Similarly, Thompson and Janigan15 developed the concept of “life schemes,” which provide a sense of order and purpose for one’s life and promotes a perspective on the world, oneself, events, and goals. Simple, open-ended questions, such as, “How is this illness affecting you?” and “How is the illness affecting the way you relate to the world?” provide the opportunity for validation and exploration of the patient’s life scheme.

### Cultural Competence

It is unrealistic to expect that health care professionals will know all of the customs, beliefs, and practices of patients from every culture. There are useful reference sources to assist in gaining cultural competence.16 However, all providers should strive for some degree of cultural competence, which has been defined as “an educational process, which includes the ability to develop working relationships across lines of difference. This encompasses self-awareness, cultural knowledge about illness and healing practices, intercultural communication skills and behavioral flexibility.”17

The members of the health care team can increase their cultural competence by concentrating on the following:

- Being aware of one’s own ethnocentrism.
- Assessing the patient’s and family’s beliefs about illness and treatments.
### General Principles

- Conveying respect, such as saying, “I am unfamiliar with your culture. Please help me understand why you think you got sick and what you think will make you better.”
- Soliciting the patient and family as teachers and guides regarding cultural practices.
- Asking about the patient’s personal preferences and avoiding expectations for any individual to represent his or her whole culture.
- Respecting cultural differences regarding personal space and touch, such as requesting, “Whom do I ask for permission to examine you?” and “May I touch you here?”
- Determining needs and desires regarding health-related information, such as asking, “When I have information to tell you, how much detail do you want to know and to whom do I give it?”
- Noting and affirming the use of complementary and integrative health care practices.
- Incorporating the patient’s cultural healing practices into the plan of care.
- Responding to resistance from the patient and family about the recommended treatment plan with understanding, negotiation, and compromise.
- Being sensitive to the need for interpreter services (Table 3–5).

### Physical Assessment at Diagnosis

When the patient has finished telling his or her story about the illness, the nurse needs to do a head-to-toe physical assessment. This assessment uses the general categories of head and neck, shoulders and arms, chest and spine, abdomen, pelvis, legs and feet, and overall evaluation. The nurse obtains data by observing, interviewing, and examining the patient. The forms, policies, procedures, and expectations of the health care agency in which the assessment occurs guide the specific details that are collected and documented. Figure 3–2 shows cues to guide the physical assessment.

Because the family is so important to the palliative care focus on quality of life, the overall health of other family members needs to be documented. Identification of the major health problems, physical limitations, and physical strengths of family members serves as a basis for planning. The physical capabilities and constraints of the caregivers available to assist and support the patient may affect the plan of care, especially in relation to the most appropriate setting for care. This information also provides direction for the types of referral that may be needed to provide care.

### Psychosocial Assessment at Diagnosis

The primary psychosocial feature of a new diagnosis is anticipatory grief. Patients’ responses to receiving bad news range from shock, disbelief, and denial to anger and fatalism. As further losses occur along the illness continuum, this grief mechanism is retriggered, and losses become cumulative. Statements such as, “I can’t believe this is happening to me” or “Why is this happening to us?” are signals to the health care professional that the patient and family are grappling heavily with this threat to their equilibrium. There is already a sense that life will be forever changed. A longing emerges to return to the way things were.

In response to these emotional states, the health care team is most helpful when they do the following:

- Normalize the patient’s and family’s experiences: “Many people share similar reactions to this kind of news.”
- Use active listening skills to facilitate grief work: “Of all that is happening to you right now, what is the hardest part to deal with?”

### Table 3–5

**Meeting the Need for Interpreter Services**

A child or family member should not be used as an interpreter for major explanations or decision-making about health care. Even adult children may feel uncomfortable speaking with their parents or grandparents about intimate topics. Furthermore, many lay people do not know or understand medical terms in their own language. Informed consent requires that the patient receive accurate information that he or she can understand, before making a health care decision.

It is recommended that the health care team obtain the services of a certified medical interpreter, if possible.

In the absence of an on-site certified translator, use AT&T interpreters. In the United States or Canada, call 1-800-752-6096 to set up an account and obtain a password.
**Head & Neck:**

/Urine Hx of UTIs? Incontinence? Other problems?

Male= TSE? DRE? PSA? Hx BPH? Meds?

Hernia? Sexually active? Hx STDs?

Contraception? Circumcised? Sexual function concerns? Impotence?

Importance to self concept, relationships, & quality of life?

Female= Gx Px? Contraception? LMP?

Menarche age? Usual menses cycle?  
Break through bleeding? Menses pain or problems? Menopause - age? ERT?

Pelvic exam & PAP smear? Vaginal discharge, dryness, odor, infection?

Sexually active? Sexual function concerns? Importance to self concept, relationships, & quality of life?

**Figure 3-2.** Assessment at the time of diagnosis: obtaining a baseline of the patient's health status. Abbreviations: ABCD = How to assess a skin mole (Asymmetry; Borders, regular or irregular; Color, multicolored; Diameter, generally >6 mm); ADLs = activities of daily living; BP = blood pressure; BPH = benign prostatic hyperplasia; BSE = breast self-exam; CAD = coronary artery disease; CHF = congestive heart failure; CP = chest pain; CXR = chest x-ray; DOE = dyspnea on exertion; DME = durable medical equipment (e.g., wheelchairs, walkers, hospital beds, etc.); DRE = digital rectal exam; EKG = electrocardiogram; ERT = estrogen replacement therapy; Gx = gravida (number of pregnancies); Px = parity (number of deliveries past 20 weeks, number of abortions).
• Create a safe space for self-disclosure, and build a trust relationship: “No matter what lies ahead, you will not face it alone.”
• Develop a collaborative partnership to establish a mutual plan of care: “What would help you the most right now?”
• Respect the patient’s or family’s use of denial in the service of coping with harsh realities: “It must be hard to believe this is happening.”
• Assess the patient’s and family’s coping styles: “When you have experienced difficult times in the past, how did you get through them?”
• Reinforce strengths.
• Maximize a sense of control, autonomy, and choice.
• Assess the patient’s need for information: “What do you know about your illness?,” “Are you the kind of person who likes to know as much as possible, or do you function on a need-to-know basis only?,” “What would you like to know about your illness now?”
• Check the need for clarification: “What did you hear?” or “Summarize in your own words how you understand your situation now.”
• Avoid “medspeak,” which is medical terminology unfamiliar to the average person.
• Mentor patients and families who have had little experience with the health care system, including coaching them in conversations with their physicians and teaching them ways to be wise healthcare consumers.

The nurse must remember that, while the patient is feeling strong emotions, the family is also experiencing intense feelings. Similar assessments of family members will help to mobilize resources at critical times. Family members experience their grief reactions at their own individual rates throughout the course of the illness. Each family member has his or her own particular coping style and need for information.

The nurse and other members of the health care team assist the patient and family when they do the following:
• Observe changes in family members’ roles and responsibilities (e.g., the breadwinner becomes a caregiver, the homemaker begins working outside the home).
• Identify external community support systems.
• Assist the patient and family in identifying coping strategies to use while awaiting test results, which is one of the most stressful times and which recurs throughout the illness.

### Table 3–6

<table>
<thead>
<tr>
<th>Common Responses of Children to Serious Illness in the Family</th>
</tr>
</thead>
<tbody>
<tr>
<td>Magical thinking that results in feelings of guilt (e.g., “I once told Mommy I wished she were dead.”)</td>

</table>

- Help the patient and family explore the benefits and burdens of various treatment options when changes are needed in the plan of care.
- Assess parental readiness to assist children with their adaptation needs: “How do you plan to tell your children?”
- Identify family communication ground rules and seek to improve communication among family members: “Is it OK if we discuss this subject with you and your family?”

Assess the coping of children within the family by being aware of their fears and concerns. Table 3–6 describes some common responses of children to having an adult loved one who is ill.

Assisting in the process of making initial treatment decisions can be an opportunity to begin a relationship that will continue to grow. Members of the health care team may ask questions such as, “What is most important to you in life?” and “Is quality of life or quantity of life most meaningful?” Assisting the patient and family in identifying and expressing their values will guide them in subsequent decision-making.

### Spiritual Assessment at Diagnosis

The diagnosis of a serious illness generally brings with it a sense of shock to the patient and family. It may threaten many of their assumptions about life, disrupt their sense of control, and cause them to ask “Why?” The health care team can be most helpful at this time if they do the following:

- Help the patient and family explore the benefits and burdens of various treatment options when changes are needed in the plan of care.
- Assess parental readiness to assist children with their adaptation needs: “How do you plan to tell your children?”
- Identify family communication ground rules and seek to improve communication among family members: “Is it OK if we discuss this subject with you and your family?”

Assisting in the process of making initial treatment decisions can be an opportunity to begin a relationship that will continue to grow. Members of the health care team may ask questions such as, “What is most important to you in life?” and “Is quality of life or quantity of life most meaningful?” Assisting the patient and family in identifying and expressing their values will guide them in subsequent decision-making.
• Determine the patient’s and family’s level of hopefulness about the future: “What are you hoping for?” or “How do you see the future at this time?”
• Inquire about how the patient and family have dealt with past crises of faith, meaning, or loss: “What helped you get through that?”
• Determine the patient’s and family’s comfort level in talking about the spiritual life: “Some people need or want to talk about these things; others don’t. How is it for you?”
• Inquire about spiritual support persons available to the patient and family (e.g., pastor, rabbi, counselor, spiritual advisor).
• Determine the patient’s or family’s need or desire to speak with a spiritual support person.
• Ask about spiritual self-care practices to promote healthy coping: “How are you taking care of yourself at this time?”
• Listen for comments from the patient and family regarding the importance of their religious traditions and practices.

Spiritual goals at this phase are to normalize initial concerns, to provide information that fosters positive coping, and to encourage the patient and family to seek supportive spiritual resources.

CASE STUDY
Ghedi at the Time of Diagnosis of Colon Cancer

Ghedi was reluctant to seek medical attention for his increasing gastrointestinal problems. He found American health care confusing and did not want to rely too heavily on his brother, Asad, to navigate the system for him. He did not want to appear weak and in need of assistance. Initially, Ghedi relied on traditional treatments provided by one of the elders in their community. As his gastrointestinal problems persisted, he finally agreed to allow his brother to make an appointment for him with Asad’s primary care physician. At this point, Ghedi was experiencing severe diarrhea and pain in the lower abdomen. An x-ray film revealed an apparent mass in the colon; a colonoscopy and biopsy were performed. Ghedi was referred to Dr. Yang, a surgical oncologist, for further evaluation and treatment. This specialist recommended complete removal of the mass, which would probably necessitate a colostomy. After much ambivalence and discussion, Ghedi agreed.

The ostomy nurse, Mindy, met with Ghedi before the operation to identify the best stoma site. As she explained what she was going to do, Ghedi refused to let her touch him. Asad explained to Mindy that his brother would not allow a woman to examine him. Remaining sensitive to Ghedi’s cultural background, Mindy called the male resident and guided him in marking the correct stoma placement.

The goals at this phase of care are to

• Use a certified medical interpreter for information-giving, decision-making, and completion of consent forms.
• Build trust with Ghedi and Asad by encouraging the integration of their native healing practices into the plan of care and by respecting their cultural boundaries.
• Determine who among his male support network Ghedi would allow to assist him in learning how to care for his colostomy after surgery. (Ghedi would not permit his sister-in-law, Laila, to assist him in any way.)
• Communicate Ghedi’s cultural preferences to other members of the health care team.

Assessment During Treatments

The goals of a palliative care assessment during active treatment are as follows:

1. Assess the patient’s systems in all domains that are at risk for problems, considering both the patient’s baseline problems and any side effects of the treatments.
2. Record the current and potential problems and plan early interventions with the patient and family.
3. Ascertain the need for teaching to prevent, minimize, and manage problems with the goal of maximizing quality of life.
4. Reinforce patient and family strengths, healthy habits, and behaviors to maximize well-being.
5. Recognize when other health care professionals’ expertise is needed and make appropriate referrals (e.g., physical therapist, pharmacist).

Physical Assessment During Treatments

Reassessments during treatment determine the changes that have occurred since the initial assessment. Knowledge of the usual disease process and the side effects of treatment assists the nurse in focusing reassessments on those body systems most likely to be affected.

In addition to the patient’s physical assessment, the nurse should make periodic observations and inquiries about the health of other family members. It is important to document any changes in their health problems or physical limitations and physical strengths that might have an impact on the patient’s care and the family’s overall quality of life.

Psychosocial Assessment During Treatments

Once a treatment plan has been initiated, patients often express relief that “something is finally being done.” Taking
action frequently reduces anxiety. The most important psychosocial intervention at this stage is the amelioration of as many treatment side effects as possible. After basic needs for physical well-being are assessed and symptoms are controlled, the patient is able to explore and meet higher needs, including the needs for belonging, self-esteem, and self-actualization. Patients who are preoccupied with pain and nausea or vomiting have no energy or ability to explore the significance of their illness or their feelings about it. Effective management of physical symptoms is mandatory before the patient can begin to work on integrating the illness experience into the tapestry of his or her life.

After several months or years of treatment, the effects of having a chronic illness may exhaust even the hardiest person. Patients may begin to weigh the benefits versus the burdens of continuing aggressive therapies. Initially, patients will endure almost anything if they believe a cure is possible. As time unfolds, their attitudes may change as they watch their quality of life erode with little prospect of a more positive outcome. Patients may also reprioritize what is most important to them. For example, the workaholic may find less satisfaction at the office, or the homemaker may experience less fulfillment from daily routines around the house. Change, transition, and existential questioning characterize this phase.

The nurse and other members of the health care team will assist the patient and family when they do the following:

- Inquire about the patient’s newly emerging identity as a result of the illness: “What activities and which relationships bring you the most joy and meaning?” or “Have you been able to define a new purpose for yourself?”
- Assess for signs of anxiety and depression, which remain the two most common psychosocial problems associated with severe illness (Table 3–7); for more information contrasting anxiety and depression, consult Holland’s Psychosocial Oncology.5
- Screen for suicidal ideation in cases of depression: “Have you been feeling so bad that you’ve been thinking of a way to hurt yourself?” and “Do you have a plan for how to do it?”
- Refer for counseling and possible psychotropic medication to enhance positive coping and comfort.

**Spiritual Assessment During Treatments**

With the treatment of a serious illness comes the introduction of an additional stressor to the patient and family. It is important to assess how they incorporate the demands of treatment into their daily routine and how these changes have affected the meaning of their lives.

The nurse and other members of the care team will be helpful to the patient and family if they normalize the stress of treatment and do the following:

- Inquire about the patient’s and family’s hopes for the future.
- Assess the level and quality of support they are receiving—for instance, from other family members, faith community, and neighbors.
- Explore expressions of anxiety and fear by asking, “What is concerning you the most at this time?”
- Assess how the patient and family are coping with the rigors of treatment: “What is the most challenging part of this for you?” and “What is helping you day by day?” Consider referrals to a chaplain or faith community as needed.

</table>
The health care team’s goals are to reinforce positive coping, mobilize existing spiritual resources, invite the patient and family to develop new skills for self-care, and continue disclosures in an atmosphere of trust.

**Case Study**

**Ghedi During Treatments for Colon Cancer**

A few weeks after surgery and the colostomy, Ghedi started on the recommended regimen of chemotherapy. He experienced side effects of diarrhea, nausea, and vomiting. He insisted on the addition of traditional “fire burning” from the Somali elder, who was also the community’s traditional Somali physician. Ghedi took several herbal preparations designed to ease his digestive problems. The clinic pharmacist determined that the herbs were compatible with Ghedi’s chemotherapy drugs. Between treatments, Ghedi received follow-up care from a home care agency. Asad specifically requested a male nurse and male aide to provide Ghedi’s personal care.

Throughout Ghedi’s treatment, Asad and the elder were in attendance and Ghedi increasingly depended on them to assist with decision-making. He exhibited a stoic demeanor, and although the medical team believed he might have been experiencing pain, Ghedi insisted he was not.

The goals at this phase of care are to

- Ask Asad and the Somali elder to assist the health care team in assessing Ghedi’s degree of pain and discomfort from the side effects of the chemotherapy. Suggest that the health care team encourage Asad and the elder to give Ghedi permission to take the pain medication.
- Continue to respect Ghedi’s cultural modesty and try to accommodate his request for male health care providers.

**Assessment After Treatments (Long-Term Survival or Terminal Phase)**

The goals of a palliative care assessment after treatments are as follows:

1. Examine the benefits and burdens of all interventions to manage the residual symptoms remaining from the treatments and/or the disease process.
2. Determine the current physical problems that are most distressing to the patient and family, and plan rehabilitative interventions.
3. Assess learning needs and provide teaching to aggressively manage problems with the goal of maximizing quality of life.
4. Continue to reinforce patient and family strengths, healthy habits, and behaviors to enhance well-being and to prevent problems.

Survivors are defined as those patients whose diseases are cured, who go into long remissions, or who become chronically ill. These individuals may require some degree of palliative care for the rest of their lives. Examples of survivors likely to require palliative care include those with graft-versus-host disease (GVHD), irreversible peripheral neuropathies, or structural alterations of the integumentary, gastrointestinal, and genitourinary systems (e.g., mastectomies, amputations, colostomies, ileostomies, laryngectomies).

Psychosocial issues for survivors include fear of recurrence as well as practical considerations such as insurance and job discrimination. Many patients make major life changes regarding work and relationships as a result of their illness experiences. These patients, even if cured, live with the ramifications of the disease and its treatment for the rest of their lives.

Some patients begin to explore, in new ways, the spiritual foundations and assumptions of their lives. Often, patients relate that in spite of the crisis of an illness and its treatment, the experience resulted in a deepened sense of meaning and gratitude for life. Examples of such growth experiences as a result of surviving cancer can be found in *Cancer as a Turning Point: A Handbook for People with Cancer, Their Families and Health Professionals* and *Silver Linings: The Other Side of Cancer.*

**Physical Assessment After Treatments**

The patient is reassessed after treatments are finished to determine the changes that have occurred since previous assessments; the focus is on the systems that have been affected and altered by the treatments. Thorough assessment of the residual problems and changes in the patient’s body are critical to successful symptom management. Effective management of symptoms with rehabilitative interventions achieves the goal of maximizing the patient’s and family’s quality of life, whether in long-term survival or during the terminal phase. Two examples of functional assessment tools used in physical rehabilitation are the Functional Assessment of Cancer Therapy (FACT) Scale and the Rotterdam Symptom Checklist.

In addition to the patient’s physical assessment, the nurse should continue to make periodic observations and inquiries about the health of other family members. Noting changes in
family members’ health, physical limitations, and physical strengths is important to ascertain any impact on the patient’s care and the family’s lifestyle.

An emerging issue that relates to family members’ health is genetic testing for familial diseases. The health care team needs to ask patients with diseases that could have a genetic origin whether they would be interested in receiving more information. Patients or family members who desire more facts will benefit from written materials and referral to an experienced genetic counselor. Table 3–8 provides resource information on genetic counseling.

Psychosocial Assessment After Treatments

For those patients who are free of disease, palliative care focuses on posttreatment-related symptoms and fears of recurrence. For others, recurrence is most often signaled by the appearance of advancing physical symptoms. When this happens, the patient’s worst nightmare has been realized. A recurrence is experienced differently from an initial diagnosis, because the patient is now a “veteran” of the patient role and may understand all too well what the recurrence means.

Attention to concerns at this phase of illness include the following:

• Revisiting the quality versus quantity of life preferences as the patient and family weigh the benefits and burdens of treatment.
• Being sensitive to the patient’s readiness to discuss a transition in emphasis from curative to palliative care. The patient often signals his or her readiness by statements such as, “I’m getting tired of spending so much time at the hospital” or “I’ve had it with all of this.” Ask: “What has your physician told you that you can expect now?” or “How do you see your future?”
• Exploring readiness to set new goals of treatment: “I know you understand that your illness has not responded to the treatments as we had hoped. I’d like to talk with you about changing your care plan goals.”
• Beginning to discuss the patient’s preferences for resuscitation: “If your heart or lungs should stop, have you thought about whether or not you would want us to try to revive you? This means that we would shock your heart, put you on a breathing machine, and transfer you to an intensive care unit. You need to think about your desire to have such life support treatments.”
• Considering a discussion about hospice if the patient begins to question the efficacy of treatments.
• Presenting hospice as the gold standard for end-of-life care. A hospice referral should never be made as a gesture indicating that “There is nothing more that we can do for you.” The benefits of increased availability and services, such as bereavement care for the family, should be emphasized.
• Discussing the completion of advance directives: “Who would you want to make your health care decisions for you if you were not able to make them yourself?”
• Determining the patient’s and family’s interest or need for education about death and dying.
• Discerning risk factors for complicated bereavement in family members, as described in Table 3–9.

Spiritual Assessment After Treatments

After treatment, the patient embarks on a journey leading to long-term survival, chronic illness, or recurrence and the terminal phases of the illness. The nurse and other caregivers can provide valuable spiritual support at these junctures when they do the following:

• Determine the quality and focus of the patient’s and family’s hopes for the future. Listen for a transition

### Table 3–8
Genetic Counseling Information

| National Society of Genetic Counselors |
| 610-872-7608 | www.nsgc.org |

### Table 3–9
Assessment of Family Members’ Risk Factors for Complicated Bereavement

| Concurrent life crises |
| History of other recent or difficult past losses |
| Unresolved grief from prior losses |
| History of mental illness or substance abuse |
| Extreme anger or anxiety |
| Marked dependence on the patient |
| Age of the patient and the surviving loved ones, developmental phases of the patient and family members |
| Limited support within the family’s circle or community |
| Anticipated situational stressors, such as loss of income, financial strain, lack of confidence in assuming some of the patient’s usual responsibilities |
| Illnesses among other family members |
| Special bereavement needs of children in the family |
| The patient’s dying process is difficult (e.g., poorly controlled symptoms such as pain, shortness of breath, agitation, delirium, anxiety) |
| Absence of helpful cultural and/or religious beliefs |
from hoping for a cure to another kind of hope (e.g., hope for a remission, hope to live until a special family event occurs). For an in-depth, practical, and inspiring discourse on hope, refer to Finding HOPE: Ways to See Life in a Brighter Light.24

- Ask questions to foster a review of critical life incidents, to allow grieving, and explore beliefs regarding the afterlife: “What do you believe happens to a person at the time of death?”
- Determine the need and desire for reconciliation: “Are there people with whom you want or need to speak?” and “Do you find yourself having any regrets?”
- Invite a discussion of the most meaningful, celebratory occurrences in life to foster integrity, life review, and a sense of meaning.
- Assess the patient’s and/or the family’s readiness to discuss funeral preferences and plans and desired disposition of the body, as noted in Table 3–10.

The main spiritual goal of this phase of illness is to provide the patient and family a “place to stand” in order to review the past and look toward the future. This encourages grieving past losses, creating a sense of meaning, and consolidating strengths for the days ahead.

**CASE STUDY**

**Ghedi After Completion of Treatments for Colon Cancer**

After his chemotherapy was completed, Ghedi was able to return to work in the housekeeping department of his neighborhood elementary school. He was in remission for 2 years before he began exhibiting jaundice. He immediately resumed traditional Somali treatments with his elder, who prescribed habakhedi and fire-burning. Because colostomy care had been challenging for him, Ghedi wanted to avoid returning to Dr. Yang. Ghedi told Asad that Dr. Yang was too direct about his future and was offering no hope of recovery. Ghedi observed ritual prayers imploring God to heal him and relieve his suffering.

A few months after he became jaundiced, Ghedi began to complain of severe itching. He lost a great deal of weight as he experienced more frequent episodes of nausea and vomiting. One day, Ghedi passed out on the bathroom floor. Laila called Asad at work. Asad immediately came home and took Ghedi to the emergency department. Ghedi was severely dehydrated and had several abnormal electrolyte results. The emergency department physician began administering intravenous fluid and admitted Ghedi to the palliative care service. The palliative care team provided comfort medications to relieve Ghedi’s pain and symptoms. They also offered integrative therapies to relieve Ghedi’s distress. He agreed to aromatherapy, massage by a male licensed massage therapist, and music. The palliative care team worked with Ghedi, Asad, and the Somali elder to develop a plan of care after discharge. After much discussion and consideration, Ghedi and Asad agreed to hospice care at home.

The goals of this phase of care are to:

- Solicit the Somali elder’s help in determining how best to support Asad’s family in caring for Ghedi at home.
- Assist Ghedi in applying for Medicaid, because he cannot return to work.

| Table 3–10 |
| Assessment of Funeral Plans and Preferences |
| Has the patient and/or family selected a funeral home? |
| Has the patient and/or family decided about the disposition of the body: organ, eye, and/or tissue donation; autopsy; earth burial (above ground or below ground); cremation; simple disposition? |
| Has the decision been made regarding a final resting place? |
| Does the patient want to make his or her wishes known regarding the type of service, or will the family decide this? |
• Inform the hospice team of Ghedi’s desire for male health care providers and the need to include the Somali elder’s traditional healing practices in Ghedi’s hospice plan of care.

Assessment During Active Dying

The goals of a palliative care assessment when the patient is actively dying are as follows:

1. Observe for signs and symptoms of impending death, aggressively managing symptoms and promoting comfort (Table 3–11).
2. Determine the primary source of the patient’s and family’s suffering and plan interventions to provide relief.
3. Identify the primary sources of strength for the patient and family members so that they can be used to provide support.
4. Ascertain the patient’s and family’s readiness and need for teaching about the dying process.
5. Look for ways to support the patient and family to enhance meaning during this intense experience.
6. Determine whether the family members and friends who are important to the patient have had the opportunity to visit in person or on the telephone, as desired by the patient and family.

Physical Assessment During Active Dying

Physical assessment during the active dying process is very focused and is limited to determining the cause of suffering and identifying sources of comfort. Figure 3–3 shows common areas to assess in the last few days of a person’s life.

<table>
<thead>
<tr>
<th>Table 3–11</th>
</tr>
</thead>
<tbody>
<tr>
<td>Common Physical Symptoms Experienced by People Who Are Actively Dying</td>
</tr>
</tbody>
</table>

- Pain from the illness and/or immobility
- Dyspnea
- Sleepiness
- Confusion
- No interest in eating or drinking
- Gurgling sounds in the back of the throat from not being able to swallow saliva
- Agitation/restlessness/delirium
- Coolness in extremities
- Incontinence
- Skin breakdown from immobility

In addition to the patient’s physical assessment, the nurse should monitor the health of other family members to prevent and minimize problems that could compromise their health during this very stressful time.

Hospice team members have excellent skills in making palliative care assessments at the end of life. The goal of hospice is to support the terminally ill patient and family at home, if that is their wish. Many hospice teams also provide palliative care in acute care settings and nursing homes. Unfortunately, many patients die without the support of hospice services in any of these settings.

Psychosocial Assessment During Active Dying

Many people believe that the transition from life to death is as sacred as the transition experienced at birth. Keeping this in mind, the nurse can help to create a safe environment in which patients and families are supported in their relationships and the creation of meaningful moments together. The patient may also still be reviewing his or her life. Common psychosocial characteristics of the person who is actively dying include social withdrawal, decreased attention span, and decreasing ability to concentrate, resulting in gradual loss of consciousness. Experiences normally considered to be psychotic in Western culture, such as visions and visitations, are often viewed as transcendent—and normal—at this stage of life by those with strong spiritual beliefs.

Members of the health care team can assist the patient and family in the following vital ways:

• Normalize the patient’s reports of seeing deceased loved ones or visions of another world.
• Encourage continued touching and talking to the patient, even if he or she is unconscious.
• Assist communication among the patient, family members, and close friends.
• Invite family members to “give permission” to the patient “to let go,” providing reassurance that the family will remain intact and learn to deal effectively with the person’s absence.
• Assess the patient’s and family’s need for continued education about death and dying.
• Observe family members for evidence of poor coping and consider making referrals for additional support.
• Encourage family members to consider “shift rotation” in the face of lengthy, exhausting vigils at the bedside.

Spiritual Assessment During Active Dying

When the patient enters the phase of active dying, spiritual realities often increase in significance. The nurse and other members of the care team will facilitate adaptation during the process of dying and provide much valuable support when they do the following:
Head & Neck:
Mind- How important is level of alertness versus control of pain and anxiety which may cause sedation?
Hearing - What sounds most comfort the patient? Music? Family chatting nearby? The TV or radio on in the background? Someone reading to him or her? Silence?
Smell - What scents does the patient enjoy? Would aromatic lotions be soothing?
Taste - What are the patient’s favorite flavors? Would mouth care to relieve dryness be more acceptable with fruit punch or apple juice?
Mouth/Lips - Does the family/caregiver understand how to provide good, frequent mouth and lip care, especially if the patient is a mouth-breather?

Shoulders & Arms:
Does the family/caregiver understand good body alignment and several ways to position the patient comfortably? Are they following good body mechanics when repositioning the patient? Would applying aromatic lotion to hands and arms comfort the patient and give family members something meaningful to do?

Chest & Spine:
Lungs-Is the patient at high risk for death rales? Is there a Scopolamine Patch or Atropine Eye Drops in the home for immediate use if noisy respirations begin? Would oxygen help the patient breathe easier?
Heart-If pt at home, is the family prepared for the moment of death? E.g., do they know NOT to call 911! Do they have a neighbor close by to come and be with them until a HCP arrives?

Legs & Feet:
Are family members interested/concerned with learning the assessment technique of feeling the feet and limbs for coolness slowly progressing from the periphery to the center of the body during the last few hours of life?
Would applying aromatic lotion to feet & legs comfort the patient and give family members something meaningful to do?

Abdomen:
Bowels- If the patient is incontinent of stool, do family members know how to provide personal hygiene?
Do family members know how to use protective pads, adult diapers, pull sheets to keep the patient clean?
Does the family know how to make an occupied bed, using good body mechanics?
Are protective ointments needed to decrease skin breakdown if the incontinence is frequent?
If stools are frequent, can anti-diarrheals be given?

Pelvis:
Kidneys/Urine- If incontinence is present, would inserting a Foley catheter prevent skin irritation & conserve the patient’s & family’s energies?

General:
• Are the patient’s pain & other symptoms well-controlled?
• Are family members capable & comfortable with continuing to provide physical care for the patient? Are family members getting enough sleep and rest to maintain their own health? Are additional resources needed to support the family?
• Is the home the best place for the patient to die? Has the family thought about their comfort in living in the house if their loved one dies there?
• Does the family know whom to call on a 24-hour basis for advice and support?

Figure 3-3. Assessment when the patient is actively dying: determining causes of pain and discomfort and identifying sources of comfort. HCP = health care professional; pt = patient.
(Source: Courtesy of Elaine Glass, APRN, BC-PCM.)
General Principles

- Determine the need for different or more frequent visits by the patient’s or family’s spiritual support person: “Is there anyone I can call to be with you at this time?” and “Are there any meaningful activities or rituals you want to do?”
- Inquire about dreams, visions, or unusual experiences (e.g., seeing persons who have died). Normalize these if they are disclosed. Ask if these experiences are sources of comfort or fear. Encourage further discussion if the patient is interested.
- Foster maintenance of hope by asking, “What are you hoping for at this time?” Reassure the patient and family that they can be hopeful and still acknowledge that death is imminent. Moving toward a transcendent hope is vital. Observe that earlier the focus of hope may have been on cure, remission, or an extension of time. Now, hope may be focused on an afterlife, the relief of suffering, or the idea of living on in loved ones’ memories.
- Listen for and solicit comments regarding the efficacy of spiritual practices. For instance, if the patient is a person who prays, ask, “Are your prayers bringing you comfort and peace?”
- Realize that expressions of fear, panic attacks, or an increase in physical symptoms such as restlessness, agitation, pain, or shortness of breath may indicate intense spiritual distress. A chaplain’s intervention may provide spiritual comfort and assist the patient in reaching peace. This may reduce the need for medications.
- Determine the need and desire of the patient and family to engage in forgiveness, to express feelings to one another, and to say their good-byes.
- Recognize that a prolonged dying process may indicate that the patient is having difficulty “letting go,” perhaps due to some unfinished business or fears related to dying. Assist the patient and family in exploring what these issues might be. A referral to a chaplain may be very helpful.
- Encourage celebration of the life of the loved one by acknowledging his or her contributions to family members, close friends, and the community.
- Explore the need and desire for additional comfort measures in the environment, such as soothing music, devotional readings, gazing out a window at nature, or increased quiet.
- Ask the family about their anticipated needs and preferences at the time of death: “Is there anyone you will want us to call for you?” “What can the health care team do to be most supportive?” “Are there specific practices regarding the care of the body that you want the team to carry out?”

The goals of spiritual care at this phase of illness are as follows:

- Facilitate any unfinished business among the patient and significant others (e.g., expressions of love, regret, forgiveness, gratitude).
- Promote the integrity of the dying person by honoring his or her life. One way to do this is by encouraging reminiscence at the bedside of the patient, recalling the “gifts” the patient bestowed on the family—that is, his or her legacy of values and qualities passed on to survivors.
- Assist the patient and family in extracting meaning from the dying experience.
- Provide sensitive comfort by being present and listening.
- Provide information regarding bereavement support groups and/or counseling if indicated.

Case Study

Ghedi’s Death

The Somali community rallied around Ghedi and his brother to assist in offering support to supplement the care provided by the local hospice agency. Ghedi died at home, as he wanted, with his elder reciting Yasin prayers from the Quran as he lay dying. Asad’s family remained quiet at the bedside without overt expressions of grief. A male sheik prepared Ghedi’s body for burial by washing, perfuming, and wrapping it in a white cloth. Asad, Ghedi’s nephew, and two male elders from the community dug his grave. (This required special arrangements with the local funeral service.)

Because the hospice team was so effective in caring for Ghedi and his family, the Somali elder was receptive to endorsing hospice services for other terminally ill people in their community.

The goal of the final phase of family care was as follows:

- Encourage Asad’s family to accept bereavement services for the family.

Summary of a Comprehensive Palliative Care Assessment

A comprehensive assessment of the patient and family provides the foundation for mutually setting goals, devising a plan of care, implementing interventions, and evaluating the effectiveness of care. Reassessments are done throughout the patient’s illness, to ensure that quality of life is maximized (Table 3–12). Further sources of information are listed in Appendix 3–1.

Finally, as Colleen Scanlon reminds us, two of the most important assessment questions that nurses and other health care team members can ask the patient and family, regardless of the phase or focus of the assessment, are, “What is your greatest concern?” and “How can I help?”
Clinicians may find the use of an abbreviated symptom assessment form helpful to track the efficacy of palliative care interventions. Whereas pain is usually plotted along the familiar mild, moderate, or severe. These kinds of tools assist in interdisciplinary evaluation of symptoms without requiring paging through lengthy progress notes. In this way, treatment can be highly individualized and always evidence based.

### REFERENCES

### BIBLIOGRAPHY

Taylor R. Check your cultural competence. Nurs Manage 1998; 3:30–32.
Key Points

- Effective communication is essential to all aspects of palliative care.
- Listening is a valuable component of communication and is a skill that requires practice and mastery.
- Nonverbal communication is as critical as verbal communication.

A nurse uses a myriad of tools in working with patients. For patients with heart disorders, a nurse uses blood pressure cuffs, scales, and stethoscopes as tools to promote optimal pressure. For patients with diabetes, a nurse teaches how to use glucometers and interpret laboratory test values as tools for maintaining blood sugars. For patients in the intensive care unit (ICU), a nurse employs various monitoring devices to measure jugular venous pressure, oxygen saturation, and vital signs, as well as ventilators and other tubes and machines as tools to maintain vital functions. However, for palliative care patients, the fundamental tool is communication.

Communication is the foundation from which assessments are ascertained, goals of care are developed, and relationships are established. A patient with an uncertain future needs honest disclosure, to pursue realistic hopes, and the most current information, to reorganize priorities and to make adaptations in coping with his or her disease process. Effective communication is critically important to elicit the patient’s and family’s needs, to negotiate goals of care, and to help patients and family members address concerns.1 Good communication sets the tone for all aspects of care at this time of life, allowing patients to paint a picture of themselves and their priorities, values, and needs in the last stages of life. Ongoing discussion facilitates expression of feelings by patients and family members, including their sense of issues and problems surrounding a life-threatening disease and their concerns about care. This in turn creates a framework that serves as a guide for health care providers to establish priorities in care at the end of life, from which the plan of care is developed. Without effective communication, the patient’s experience of suffering is unknown, and effective symptom control is impossible.2

According to the American Nurses Association, nurses have a duty to educate patients and families about end-of-life issues, to encourage the discussion of life preferences, to communicate relevant information for any decision, and to advocate for the patient.3 However, many nurses are uncomfortable...
communicating with dying patients. Various studies have identified a lack of communication in addressing care wishes and inadequate knowledge and skill in end-of-life-care communication.\(^4,5\) The barriers to communication are multidimensional. Patients often avoid talking about their pain, anger, sense of loss, sense of guilt, and fears due to embarrassment, shyness, confusion, and cultural prohibitions. Families may be unable to talk about the advanced nature of their loved one’s illness. They may have no knowledge of the patient’s preferences for types of care. Not surprisingly, families tend to overestimate the possibility of cure and to fear experiencing future regrets if they do not pursue or demand further curative treatment.

Nursing issues in communication include fear and medical and legal issues. One concern is the supposition that bringing up issues related to dying or advanced care planning will cause emotional distress. Nurses may anticipate conflict between patient and family. They may have concerns about medical and legal issues related to their scope of practice. Yet, nurses are often the first health care providers to identify problems in regard to advanced care planning, goals of care, conflict between patient and family wishes, and use of life-sustaining measures. Moreover, Fallowfield\(^4\) suggested that some physicians believe nurses are more capable than they are of talking with distressed patients and families. However, many nurses feel uncomfortable with their communication skills, feel the pressure of too little time, or feel threatened by such conversations. Yet, in our experience, the majority of palliative care consultation is spent on discussions of care goals.

Across the palliative care spectrum, communication occurs at critical junctures. Depending on the prognosis of the patient, these communications may occur over a long or a short period of time. The initial communication consists of introduction of the nurse and patient, perhaps at the time of the initial diagnosis of a potentially life-threatening illness. During this time, the patient and nurse get to know each other. The tasks of the nurse at this stage are to elicit personality and coping styles and to explore the patient’s understanding of his or her illness. Additionally, the nurse identifies any existing advanced care planning and determines priorities and goals of the patient. The task of the patient is getting to know the nurse as a member of the health care team. This communication may proceed smoothly until the patient’s condition changes, at which time the focus of care may change. At this point, the patient seeks trust and reassurance from the nurse, including continued involvement. Later, there may be a discussion of bad news, in which the reality of the situation is addressed and mutual goals are established. During this time, conflicts may be negotiated or life-sustaining treatments discussed. The nurse may be a part of these discussions; if not, the nurse may later serve to reinforce the information. Finally, as the patient is dying, communication with the patient and family often focuses on such issues as support of decisions, continued reassurance that comfort will be maintained, and anticipatory grieving. Communication with family members continues during anticipatory grief and, after the death of the patient, during bereavement.

Within the spectrum of health care, nurses are trusted members of the health care team at the time of diagnosis, during treatment, and in the final stages of life. Through effective communication, the nurse has a pivotal role in supporting the patient. Indeed, the nurse may have the best opportunity to learn the patient’s hopes, fears, dreams, and regrets and to create a healing environment. Many nurses have not had either the training in communication as part of their education nor the luxury to work collaboratively with other health disciplines to learn these skills. This chapter reviews the fundamental elements of communication and the roles of the nurse in communicating with patients, facilitating the communication process in advanced care planning, helping to set goals, and delivering bad news. A discussion of the nursing role in collaborative care and conflict resolution is also included.

### Historical Perspective

Communication about the end of life has changed dramatically since the 1960s, when death and dying were closed, unacknowledged topics. Field and Copp\(^7\) described an interesting movement in communication with dying patients. Initially, the topic of death was avoided with patients and was discussed only among health care providers. Moreover, communication skills were considered to be intuitive or inherited traits. Practitioners either had empathetic and effective communication skills, or they did not.\(^2\) For patients being cared for by an uncommunicative or ineffective clinician, dying could be an isolating, anxious, fearful, mistrustful experience that translated into a sense of abandonment. In such a situation, families experience complex grief and bereavement and increased stress. For nurses, this indirect communication and lack of truth-telling in the dying process results in greater stress, anxiety, and inauthentic communication, which translates to guilt, internal conflict, and a sense of failure.

From the 1960s to the 1980s, the principles of informed consent and autonomy became valued in health care. In the 1990s, as truth-telling became a central focus of terminal care, death became a more open topic of discussion for patients. For better or worse, without any consideration to the uniqueness of patient/family systems, patients and families were informed of death and dying irrespective of their wishes to know such information. Active participation of patients in their care became the underlying value that led to a greater sense of control and diminished anxiety. However, this shift did not necessarily allow for the individual issues of patients to be discussed, such as whether they wanted to be involved in making decisions. Currently, the trend is a conditional process that supports the patient’s individual coping style. This allows for care to follow the patient’s individual personality, particularly in terms of the patient’s level of acceptance or denial of the dying process.

Given this need to identify and treat each patient individually, communication skills are essential to provide optimal nursing care. Interestingly, a shift in communication theory
Communication in Palliative Care

Importance of Communication

In the health care environment, communication, whether intentional or not, occurs all the time between nurses and patients in every aspect of care. Patients consider communication skills to be very important. Bailey and Wilkinson performed a qualitative study that evaluated patients’ perceptions of nurses’ communication skills and attributes of a good nurse. Twenty-nine patients were surveyed about communication. Patients specified that nurses must have good verbal and non-verbal skills and be approachable, sympathetic, and nonjudgmental as well as caring. Patients also felt that a good nurse has the personal characteristic of being a good listener and the professional quality of being a good communicator. All of these are important characteristics of general nursing. Clearly, nursing and communication at the end of life go hand in hand.

Communication needs of the nurse include skill acquisition, credible knowledge in the area of end-of-life care, empowerment to participate and communicate in death and dying discussions, and appropriate communication behaviors. Moreover, communication skills affect the success of the nurse in her various therapeutic roles, including advocacy, support, information-sharing, empowerment, validation, and ventilation.

There are two levels of necessary communication skills based on education and expertise. At the registered nurse or generalist level, critical communication skills include, but are not limited to, listening and supporting patients in coping with their disease, providing information to patients so that they can make important decisions, being present at the delivery of bad news, being present in family meetings, reinforcing information to give consistent content, reviewing options of care, supporting decision-making, advocating for the patient and family, reviewing signs and symptoms of dying, facilitating communication between the patient and family, being present in the dying process, providing postdeath care and direction, and providing support in grief and bereavement. Some generalist nurses consider the role of information sharing and any discussion of diagnosis and treatment to be outside their scope of practice. However, from the perspective of the advocacy role in nursing, information sharing empowers the patient to make informed decisions. Moreover, the very proximity of the nurse in the direct bedside caregiving role affords the nurse many opportunities to create positive communication encounters. The plethora of opportunities to begin dialogue about death and dying include, in addition to planned meetings, moments of privacy between nurse and patient during bathing, feeding, and self-care activities.

At the master’s or advanced practice level, critical nursing communication skills include discussions of diagnosis, treatment options, and prognosis; delivery of bad news when disease progresses; transition into palliative care; discussions of life-sustaining treatment; facilitation of family meetings; discussion of postdeath options such as autopsy or organ donation; and grief and bereavement support. However, the issue of which consultation is used is important to the APN. In the medical model primarily used in the academic setting, the focus is on expertise in palliative care. In the nursing model, the focus is on coaching or mentoring, depending on the culture and environment of the work setting.

Lack of education or training or lack of personal and professional experience with death and dying results in little exposure to end-of-life communication. Unless nurses are mentored or coached by colleagues, lack of confidence in performing these tasks leads to avoidance of participation in difficult communication encounters. Other nurses may have discomfort with communication in such circumstances due to personal struggles of unresolved grief, fear of their own mortality, or fear of being emotional in front of a patient. Nevertheless, in order to be effective in dealing with patients at the end of life, nurses must examine their own feelings about death and dying, receive support for their personal grief, and seek mentoring to improve communication skills.

Communication during the end-of-life period is critical. The players involved in the communication process include the patient, the nurse and health care providers, and the family or support people. Each person has different needs, related to personal communication styles and learning styles. Communication styles vary by speech, tone, intensity, amplitude, and speech patterns. Learning styles include seeing, hearing, doing, or a mixture of all three. Therefore, it may be necessary to use a variation of verbal discussion, written materials, and videos.

There are several needs of the patient, including management of symptoms, support from family and friends, fulfillment of family or cultural expectations, attaining meaning, and maintaining dignity and control. Discrete communication needs of the patient related to these issues include obtaining information, synthesizing the information, making decisions, and trying to maintain some sense of control. The nurse serves to assess these areas, particularly in times of stress, when information processing may be impaired. As Pasacreta and colleagues described, a person who is mildly anxious may be able to process information and, in fact, may be quite creative. Indeed, mild anxiety helps most people do their work by being alert to issues, identifying problems, and facilitating creative solutions. Some patients experience mild anxiety simply by participating in a preventive health encounter. In this situation, the nurse may provide basic...
health information. However, as anxiety increases toward a moderate level, as often occurs with receiving news about disease progression, information processing becomes selective. In terms of patients, this means that when something scary or threatening is communicated, the patient may not be able to take in much information. For instance, a patient may be told that an x-ray film looks abnormal. At that point, the patient has a heightened awareness and may be thinking of possible issues. In this case, the nurse provides support to the patient in allowing the patient to ventilate fears and concerns and reiterating information that the team has provided.

In cases of severe anxiety and panic, such as when hearing bad news in the form of a short prognosis or lack of options, a patient’s information processing may be totally impaired. This occurs when a patient is given a terminal diagnosis. As soon as the physician or the advanced practice nurse (APN) gives bad news of such gravity, the patient may then not be able to hear anything else. He or she may have gone into shock or panic about the news and cannot comprehend other information. This is important for the timing of further communication and follow-up of such an event. Nurses have an important role in validating the patient’s reactions and offering support in determining what further information the patient may need.

The existential aspects of end-of-life communication include disclosure, searching for meaning, and responding to grief reactions to the received information. Exploration surrounding life-threatening illnesses can help a patient live while dying, lessen fear, and achieve quality of life during this process.

The communication needs of the family and other supportive people depend on their role in the family system, age, decision-making ability, and other rules within and specific to the family. Families are often very involved in care, but they may also have multiple home and work responsibilities. Therefore, it may be a challenge for family members to be present at the bedside. Families may experience a high level of frustration from the need for constant updating of information in order to organize and prioritize other activities around their caregiving role. In an attempt to balance their self-care issues, they may not be present for important informal information sharing unless a meeting is scheduled.

To facilitate participation in the patient’s care, families need communication regarding several issues: understanding what is the care plan is, what is currently being done, and how they can be helpful; reassurance of the patient’s comfort; support in coping with the patient’s condition; and support in being with the patient. Correspondingly, the communication needs for the patient include information, ongoing explanations of the rationale for care, the need to be listened to, and the opportunity to participate in important discussions. For both the patient and the family, the nurse is the pivotal clinician in fostering the communication processes.

**Communication Framework**

Communication comprises both verbal expression, including various words and language, and nonverbal expression or the use of body language. Other aspects of communication include the educational level of content, the emotional expression, and the nature of the relationship between the sender and receiver, or between the patient and the health care provider. Communication can be affected by myriad factors including, but not limited to, education of the patient and family; literacy of the patient and family; cultural issues of the patient and family; English as first language; stress, coping, and anxiety of patient and family; use of medical jargon, particularly three-letter acronyms; and assumed common understanding of vocabulary.

Nurses often act as translators between the various health disciplines and providers and the patient/family. By the virtue of their constant bedside presence, nurses must create the optimal method of interaction with a patient. This includes assessing the patient’s coping and learning styles and discerning the patient’s ability to understand simple requests to promote healing, as influenced by his or her mental status and severity of illness. The process itself varies according to the age and cognitive development of the patient. For children and some older adults, the family or support unit is primarily involved in the information process. Their intimate proximity allows nurses to broach sensitive topics based on the hours they spend at the bedside. More specifically, according to Pierce, nurses fulfill three critical communication tasks in end-of-life care: (1) they create an environment conducive to communication, (2) they ease interaction between physician and patient, and (3) they facilitate interaction between family and patient. The case study is an example of opening dialogue.

**CASE STUDY**

**Mr. L, a Man with End-Stage Cardiac Disease**

Mr. L, a 70-year-old man with end-stage cardiac disease, has been treated with a number of medications but has been having more angina. The cardiac team has told him there is no further treatment. They said they will try to keep him comfortable but that he was to expect more pain. They are planning on sending him home with various medications and home health services in the next day or so.

**Nurse:** Hi, Mr. Jones. I will be your nurse today. How are you feeling?

**Mr. L:** I am okay, but I am in pain. So many people have been poking at me.

**Nurse:** Can you tell me a little about your pain?

**Mr. L:** My chest hurts like they said it would. But there is nothing more they can do. I guess I should just forget about it and try to make the best of it.

**Nurse:** What did the doctors tell you?
MR. L: They said it would hurt. My heart isn’t working well.
NURSE: Hmm, what do you understand about your heart?
MR. L: The heart doctors said my heart is broken and not working right. There is nothing to be done. I just have to wait till it stops.
NURSE: Well, that is a lot to take in. Let me help you understand better. It is true your heart is not working well. And it is true we cannot get it back to normal. But we can use medicines to keep you comfortable. We are not just waiting for it to stop. I could give you some medicine to help your pain now.
MR. L: You can? I thought there were no more medicines that would help.
NURSE: I can give you medicine to help the pain. It won’t fix your heart, but it will make you feel better.
MR. L: That would be good. I thought they were just waiting for me to die and didn’t want to give me pain medication until I was close to dying.

Here the nurse promotes an open environment for the patient to ask questions and clarifies communication that has occurred between the patient and the physician.

Elements of Communication

There are four basic elements to communication: imparting information, listening, information gathering, and presence and sensitivity. Realistically, these elements do not occur in a linear fashion but may occur concurrently. However, for the sake of simplicity, they are discussed separately here.

Imparting Information

As nurses, our role is to impart information. This often includes teaching, educating about illness, and providing general information about treatments. APNs may offer other information, including diagnosis and treatment options. Imparting information is complex, because information alone is not enough. Rather, information must be provided within the appropriate context of educational level, developmental level, stress level, and time constraints. The patient’s educational level and understanding of medical language affects his or her information processing. Many patients have not finished high school; they may not understand complex words, or they may not understand many English words if it is their second language. Developmental language refers to the age of the patient and his or her ability to reason. Younger children do not have complex reasoning abilities, whereas adolescents do. Information for pediatric patients and families must meet their particular needs, and the same is true for those patients with developmental delays or cognitive deficits. The stress of being in a health care setting impairs a person’s ability to process in information. The more anxious a person is, the less able he or she is to process information. Therefore, imparting information usually means providing information at a fifth or sixth grade education level and at small intervals, to allow patients and families to best hear and process what is being said.

CASE STUDY

JQ, a Young Woman with Recurrent Melanoma

JQ is a 19-year-old young adult with recurrent melanoma. She was originally diagnosed when she was 16 years of age. She underwent surgical excision and aggressive chemotherapy. She is struggling with her diagnosis.

JQ: I can’t believe this. I want to go out with my friends. I can’t be sick now. I have too much going on. They did the tests too quickly and didn’t read them properly. They will just have to redo everything as I don’t believe it.

NURSE: It must be hard to go through this.
JQ: Go through what? They just didn’t do the tests right. I plan on leaving here and I will come back when they can focus on me. There have been too many people. Besides, my parents told me not to worry.
NURSE: Can you tell me what your doctor told you?
JQ: My cancer doctor told me I was cured of cancer. But I just have a little spot on my stomach. They just need to work on it. It is no big deal.
NURSE: What is your understanding of your type of cancer?
JQ: I have melanoma, which they can cut out and give me chemotherapy. They just need to figure out what to cut.
NURSE: This must be hard to take in. Would it be helpful to set a time to talk with your doctor again?

Here the nurse listens to the patient to hear what she understands and to assess her ability to process new information. Because the young woman is having difficulty processing the news, the nurse allows her to vent and validates her feelings.

Listening

Listening is an active process that requires full presence and attention. Specifically, one both listens to the words and interprets nonverbal gestures. Often it is very helpful to hear the patient’s story in his or her own words. This allows better understanding of the patient’s journey within the disease trajectory and of how the patient is processing information. The nurse must perceive the verbal content of the patient’s responses as well as the words left unsaid. Concurrently, the nurse perceives the nonverbal expressions of emotion and of psychological or spiritual distress. In this process, the nurse listens to the patient’s words and concerns without interrupting. The use of silence is paramount. The nurse must not be mentally preparing answers or replies; rather, the nurse uses self-reflection and conveys empathy. The nurse clarifies what has been heard by such comments as, “Hmm” or, “Tell me more.” By acknowledging the
patient’s comments and emotions and exploring their meaning in a compassionate and supportive way, the nurse encourages the patient to explain difficult issues and concerns.\(^{21}\) There may be times when the patient is silent. In this circumstance, it may appropriate for the nurse to just sit quietly, letting the patient reflect on the moment and the current situation.

**Case Study**

*PM, a 21-Year-Old with a Neurogenerative Disease*

PM is a 21-year-old woman with a progressive neurodegenerative disorder that has left her quadriplegic. She has developed respiratory weakness necessitating ventilatory support. Although she did not want treatment, PM was convinced to undergo a tracheostomy with mechanical ventilatory support. She went to a rehabilitation hospital for 2 months then returned home. She is now at home and has asked the palliative care nurse (PCN) to talk with her about her situation. After introductions, the nurse and the patient begin talking.

**PCN**: PM, how are you doing?

**PM**: I am stuck. I am on the breathing machine. I had this trach done because they told me I would have a better life. Nothing has changed. I cannot leave this room. I am not going to get better, I will only get worse. I can still talk a little now, but for how long? How long do I have to suffer like this?

**PCN**: PM, you have been thinking a lot about treatment. You said you are suffering. Can you tell me more?

**PM**: This is suffering. I have nothing to look forward to. I will never be able to walk. I cannot eat; I need this tube. Soon I will not be able to talk. This is not what life is about.

**PCN**: Hmmm.

**PM**: My parents are exhausted because they must do everything for me. Can you imagine what it is like to be in my body? There is no pleasure or joy. I cannot go on like this. I do not want to live by machines. I want to be able to do more. However, I cannot. I was talked into having this trach. But it has brought more grief. It is the big monster that controls my life. I want to take control. I want to be the one who shuts down the machine, not the other way around. (Tears roll down her face.)

**PCN**: (Silence)

**PM**: I am tired of living like this. Please help me take control by withdrawing the vent.

**PCN**: I can hear your suffering. This must be very difficult. When you talk about withdrawing the vent, do you understand what it means?

**PM**: It means I will die. I have thought about it. This is not quality of life. Can you understand that?

**PCN**: (Nods yes)

**PM**: Could you live like I am and think it is quality of life? I don’t want to be like this. Please help me.

Here the nurse listens to the patient and her language. She shows that she is really listening by using the patient’s own words and having the patient define what she means. The nurse also provides support by not trying to have all the answers and by letting the patient guide the conversation.

**Information Gathering**

To gather information from patients, the use of open-ended questions is most effective. This allows the patient to tell his or her story in narrative. During this process, the nurse therapeutically uses open-ended questions rather than “yes-or-no” questions or closed-ended questions. Open-ended questions allow the patient to tell his or her story, whereas closed-ended questions limit the patient’s answer and thereby inhibit elaboration, explanations, and clarifications from the patient. Open-ended questions promote a richness in hearing the patient’s words and nonverbal cues, which express issues of importance and priorities of care.\(^{26}\) Open-ended questions may take many directions in terms of coping, life priorities, and spiritual concerns.

A nurse may not be able to ask many questions. However, a few key questions can set a tone of a caring relationship with the nurse. See Table 4–1 for a list of questions. Once such a question is asked, it is essential to listen to the answer. Often important questions are asked, but, as the patient starts to answer, the conversation moves on, with no time or attention being given to hearing what the patient is expressing, no further elaboration, and no response to the patient’s verbal and nonverbal messages. This can cause resentment in the patient if he

or she has shared something intimate without acknowledgment as to its significance. The following is a sample of the use of open-ended questions.

**Case Study**

*Ms. M, a Woman with Metastatic Ovarian Cancer*

Ms. M is a 50-year-old woman with metastatic ovarian cancer. She has no further treatment options. However, she has come in for thoracentesis and paracentesis.

**Nurse:** How are things going at home?

**Ms. M:** It is really hard. I am in more pain. I can’t get around as much. I hate staying in bed. I feel like a burden to my family.

**Nurse:** In what way are you a burden?

**Ms. M:** I have to ask them for everything. They must bring me my pills, bring me meals. They must even help me to the bathroom. It is so embarrassing. I used to take care of them. Now they must help me. It doesn’t seem fair. How can I keep doing this to them?

**Nurse:** What do you feel you are doing to them?

**Ms. M:** I am making them focus on me instead of their lives. It is not fair.

**Nurse:** What is giving you strength?

**Ms. M:** I am not sure. I used to think my religion did. Now I don’t know, because it makes no sense.

**Nurse:** What makes no sense?

**Ms. M:** This disease. How did this happen?

**Nurse:** (Quiet)

**Ms. M:** This disease stinks and it is making me rethink all sorts of things I took for granted.

**Nurse:** Like what?

**Ms. M:** All the things I thought I would do and can’t.

**Nurse:** What were those things?

**Ms. M:** Getting my family in order.

**Nurse:** How can we help you to still do some of those things?

**Ms. M:** I am not sure, but I will think about it.

Here the nurse promotes open dialogue by asking open-ended questions to learn more about the patient and her coping.

**Sensitivity**

Sensitivity, another term for cultural competence, includes issues pertaining to religious, spiritual, cultural, ethnic, racial, gender, and language issues and is a very important element of communication. Not only is it important to appreciate verbal cues, but also it is critical to interpret nonverbal cues. Communication varies in different cultures. In many situations, beneficence takes precedence over autonomy. Disclosure and nondisclosure must be viewed within the context of the patient and the family, with understanding of and respect for their values and beliefs.

| Table 4–2 |
| Useful Cultural Assessment Questions |
| Where were you born and raised? |
| What do you want to know about your medical condition/illness? |
| How do you describe your medical condition/illness? |
| How have you treated your medical condition/illness? |
| Who else, if anyone, do you want to know about your medical condition/illness? |
| Who else, if anyone, should we talk to about your medical condition/illness, treatment options, and the disease process? |
| Who is responsible for your health care decisions? |
| Who are important people in your community? |
| What do you fear most about your condition and its treatment? |

**Source:** Adapted from Lapine et al. (2001), reference 28; Kagawa-Singer and Blackhall (2001), reference 29; and Buchwald et al. (1994), reference 30.

In these situations, nurses must first examine their own cultural backgrounds and be aware of their own ethical values and beliefs. Then, they can assess the communication patterns of the patient and the family, using questions from Table 4–2. For example, the nurse may ask the patient how she wants to receive medical information. The patient may state she wants to hear it directly, or she may defer to family members. Next, the nurse helps the patient identify others whom she wishes to be told about her medical issues. The nurse then may help the patient state who she wants to make health care and treatment decisions.

If the patient and family do not speak English as a first language, it is incumbent to use an interpreter for any discussions. Too often, family members are asked to interpret from English to another language, which puts them in a double bind. Culturally, although they may be translators, they must also act within their family roles and may need to protect the patient from information depending on cultural norms. Translating family members may withhold information if they are not comfortable with another family member knowing it. As a result, it may be very unclear what the patient has actually been told.28 For this reason, a translator not known by the family must always be used. The following example demonstrates how a nurse may facilitate appropriate cultural care.

**Case Study**

*Mrs. C, a Woman with End-Stage Renal Disease*

Mrs. C is a 75-year-old Chinese woman with end-stage renal disease who is starting dialysis. She was admitted for weakness, pain, and anorexia. Her dialysis nurse meets her when she comes to start dialysis while still in the hospital.
Methods and Techniques of Communications

The context in which communications occur, including the verbal and nonverbal content of messages, the tone, and the emotional affect of the participants, influences the process and outcomes of interactions. Important information is best conveyed face-to-face, allowing observation of verbal as well as nonverbal communication by various team members. Scheduled meetings are good for both patients and health care providers. For the interdisciplinary health care team, scheduled meetings allow for preparation of the important information to be shared, including medical facts, prognosis, treatment options, and sources of support and guidance. They promote collaborative care by allowing the team (nurse, physician, social worker, and other clinicians) to review the information in order to provide a unified and consistent message to the patient and family. They also allow the bedside nurse to organize his or her day so as to be part of these important discussions.

The timing of communication is important. Quill and colleagues33 defined the following “urgent” situations that necessitate immediate communication: (1) the patient is facing imminent death; (2) the patient is talking about wanting to die8; (3) the patient or family is inquiring about hospice; (4) the patient has recently been hospitalized for severe, progressive illness; and (5) the patient is experiencing severe suffering and poor prognosis. Less urgent situations that require more routine planned meetings include (1) the discussion of prognosis, particularly if life expectancy is thought to be between 6 and 12 months; (2) the discussion of treatment options with low probability of success; and (3) the discussion of hopes and fears. End-of-life communication in more “routine” circumstances, when stability or recovery is predicted, normalizes the discussion of advanced care planning. These discussions assist the determination of the patient’s values, goals, fears, and concerns while also developing the core issues for patient education, including the right to high-quality pain control and symptom management.27

Scheduled meeting times are critical in allowing the patient to prepare emotionally and psychologically for any potential news. This includes allowing for the presence of the patient’s support network to hear and validate information conveyed. Nurses play a vital role in these meetings because they are often responsible for arranging the meeting and securing a comfortable space. Before the meeting, the nurse may assess the patient’s physical, emotional, and psychological concerns. This information can assist the team in planning discussion points at the scheduled meetings.

When such a meeting occurs, several steps are important. After introductions have been done, the goals of the meeting can be stated. Then the patient can be asked about his or her understanding of the medical condition and situation. This is followed up by ascertaining the patient’s worries and fears, how much information the patient wishes to know,15 and which other people the patient wishes to be informed or
involved in his or her care. A patient who is hesitant to express emotional concerns may need prompting or an invitation to speak. With overbearing families, it may be important to reinforce the goals of the meeting and to restate that the focus of care is on the patient. The nurse may facilitate the initial conversation by serving as a reference point for the patient and family in conveying important conversations and concerns at the beginning of the meeting and personalizing the discussions to the specific needs of the patient and family. In addition, the nurse may act as a translator between the medical team and the patient, facilitating information sharing, interpreting information and medical jargon in language the patient understands, and also ensuring that the members of the care team understand the patient’s words and language.

CASE STUDY
KZ, a Woman with Metastatic Nerve Sheath Tumor

KZ is a 30-year-old woman with metastatic nerve sheath tumor. She has undergone multiple surgeries, various chemotherapy regimens, and some radiation. KZ is cared for at home by an extended family. Her oncology nurse practitioner (ONP) was called to the home by the home health nurse because KZ’s condition was declining. KZ is bedbound, with lower extremity paralysis and left hip pain. After much discussion and consideration, she is brought to the hospital for symptom management and transition of care. A meeting is scheduled by the ONP with the oncologist, the primary nurse, and the palliative care nurse practitioner. The goal of the meeting is to discuss code status and further treatment. At the meeting, KZ is in her bed surrounded by her many family members and the health care team. The oncologist reviews her cancer and treatment to date. Then the ONP begins her part of the discussion.

ONP: K, I have been concerned about you. I brought you into the hospital because you were in so much pain. I am wondering how you are doing.

KZ: Well, it has been okay. But this pain is incredible. Do you think you can make it better?

ONP: I think we can. We will have you evaluated by a team that specializes in pain control. However, I am wondering how you are doing with your cancer?

KZ: Well, I know it is still there, and I would like to continue treatment.

ONP: When we saw you last time, we discussed that the common chemotherapies were not working. We discussed some experimental treatment. Do you remember that?

KZ: I do, and I want to continue treatment.

ONP: Do you remember when we discussed further chemotherapy, we also discussed functional status? I am concerned because you are hardly able to get out of bed.

KZ: I will be okay soon. I can do it.

ONP: K, do you remember when we met you said you wanted me to be direct and honest with you.

KZ: Yes.

ONP: Well, I need to be honest now. I am not sure you will be able to tolerate more treatment. I think things are changing.

KZ: What do you mean?

ONP: K, remember that the last time you were here your cancer had grown. I am sorry but I have to tell you it is still growing. We are concerned that giving you more chemotherapy would do more harm than good now. Is that true, Dr. J?

DR. J: K, I know you want to be cured. But as we discussed last time, when the other chemo didn’t work, we don’t have very many options. None of the chemotherapies we give you now will cure you. It may have a very small chance as slowing the growth.

KZ: I can still do it. I will be okay.

DR. J: K, you are weak and having so many side effects that I can’t offer it right now. If you get stronger, we may be able to do it. But right now, you have to take an ambulance to get here.

ONP: Dr. J and I have been discussing this, and we are afraid the side effects are too great. We would like to focus on your comfort.

KZ: If I get better, would you still give me chemo?

ONP: If you got better we would still give you chemotherapy, but we don’t think that will happen. We would like to have palliative care work with us to focus on your comfort.

KZ: I just want you to stay involved in my care.

Here the ONP builds on her strong relationship with the patient as well as referring to previous conversations to convey bad news and to reassure the patient of nonabandonment. Effective communication, as viewed by terminally ill patients, their families, and health care professionals, primarily consists of providing accurate information in a sensitive, simple, and straightforward manner and in understandable language. Studies indicate that patients want their physicians to be honest and straightforward as well as hopeful, and this also can be applied to nurses. Therefore, the nurse should encourage patients, their families, and health care professionals, primarily to focus on their comfort.

KZ: I will be okay soon. I can do it.

ONP: K, do you remember when we met you said you wanted me to be direct and honest with you.

KZ: Yes.

ONP: Well, I need to be honest now. I am not sure you will be able to tolerate more treatment. I think things are changing.

KZ: What do you mean?

ONP: K, remember that the last time you were here your cancer had grown. I am sorry but I have to tell you it is still growing. We are concerned that giving you more chemotherapy would do more harm than good now. Is that true, Dr. J?

DR. J: K, I know you want to be cured. But as we discussed last time, when the other chemo didn’t work, we don’t have very many options. None of the chemotherapies we give you now will cure you. It may have a very small chance as slowing the growth.

KZ: I can still do it. I will be okay.

DR. J: K, you are weak and having so many side effects that I can’t offer it right now. If you get stronger, we may be able to do it. But right now, you have to take an ambulance to get here.

ONP: Dr. J and I have been discussing this, and we are afraid the side effects are too great. We would like to focus on your comfort.

KZ: If I get better, would you still give me chemo?

ONP: If you got better we would still give you chemotherapy, but we don’t think that will happen. We would like to have palliative care work with us to focus on your comfort.

KZ: I just want you to stay involved in my care.

Here the ONP builds on her strong relationship with the patient as well as referring to previous conversations to convey bad news and to reassure the patient of nonabandonment.
information, it is helpful to ask for specifics about the conversation, in terms of what and how information was conveyed as well as the patient’s response. This allows the nurse to follow up with the patient’s perception of the information and his or her understanding of the next steps.

The actual process of conducting a meeting at which important information is to be conveyed has seven steps:\(^1\) confirming medical facts and establishing an appropriately private place and sufficient time for discussions, \(^2\) using open-ended questions to establish what the patient (and family) knows, \(^3\) determining how the patient wishes the information to be presented, \(^4\) presenting information in a straightforward manner, using understandable language, in small quantities and with pauses for processing and questions to assess understanding, \(^5\) responding to emotions, \(^6\) clarifying goals of care and treatment priorities, and \(^7\) establishing a plan.

Quill\(^27\) emphasized the importance of these end-of-life conversations in their early, systematic occurrence. He described how the early introduction of such conversations in the disease process promotes better outcomes. These outcomes include more informed choices, better palliation of symptoms, and more opportunity for resolution of important issues.\(^27\) Such questions as, “Are there things that would be left undone if you were to die sooner rather than later?” stimulate thought and discussion about dying and important life closure issues such as healing relationships and completing financial transactions. However, a nurse may ask this in a different way, such as, “Are there things you need to do in case things do not go as well as we hope?”\(^29\) Encouraging patients to hope for the best outcome while preparing for the possibility that treatment may not work is helpful in guiding the patient.\(^40\) Again, the nurse advocate role facilitates the essential process of providing the patient with all the necessary information to make choices.

### Case Study

**Mrs. D, a Woman in Respiratory Distress**

Mrs. D, a 40-year-old woman, was in the ICU for respiratory distress. Her history included obesity, chronic obstructive pulmonary disease, emphysema, and cardiomyopathy. She was taking four inotropes to stabilize her blood pressure and multiple medications for respiratory support. Her breathing was so compromised that it was difficult for her to talk for long. The cardiac team had offered her the surgical option of a heart repair. She had consented, but it was very clear that she did not understand the risks. First, she might not be able to undergo intubation, and that would preclude surgery. Second, she might be intubated and not be able to be extubated. Third, anesthesia might go well, but the cardiac team might find that they could not help her. Fourth, she might die during the procedure. Fifth, even with the procedure, the inotropic and respiratory support might not make her situation better, and she might not make it home. The palliative care team was called in to see this woman. Her room was dark, and it was clear that she was afraid, depressed, and anxious.

**Nurse:** Mrs. D, I am a nurse with the pain and symptom team. Your physician asked that I come talk to you to make sure we were keeping you comfortable. Is this an okay time to talk?

**Mrs. D:** (Nods “yes”)

**Nurse:** I don’t want to increase your work of breathing while we talk, so I am going to ask simple questions. To begin with, I notice you have been in the ICU awhile. It must be hard to be here and not at home.

**Mrs. D:** (Nods yes and then tears up).

**Nurse:** Is getting home really important?

**Mrs. D:** Yes, I need to take care of my children.

**Nurse:** What have the doctors told you about going home?

**Mrs. D:** They told me I need an operation, and then I can go home.

**Nurse:** How do you feel about that?

**Mrs. D:** I am scared.

**Nurse:** What are you scared about?

**Mrs. D:** That I won’t make it.

**Nurse:** That must be hard.

**Mrs. D:** I am so scared. I don’t know what to do.

**Nurse:** How can I help you?

**Mrs. D:** Tell me about the operation.

**Nurse:** What do you know about the operation?

**Mrs. D:** They said they would repair my heart.

**Nurse:** Yes, that is true.

**Mrs. D:** But they said it was complicated, but I don’t know why. What is wrong?

**Nurse:** You are right about the operation. It is very complicated. Would you like me to explain it all?

**Mrs. D:** Yes.

**Nurse:** You understand your heart is not working correctly, right?

**Mrs. D:** (Nods yes).

**Nurse:** But they want to fix it. However, there are other parts to the operation. Did they tell you about the process of the operation?

**Mrs. D:** No (shaking her head).

**Nurse:** Do you want to know?

**Mrs. D:** Yes. My children keep asking me.

**Nurse:** Well, they will need to put you to sleep. That may be hard with your breathing issues.

**Mrs. D:** What else . . .

**Nurse:** Then they will need to get to your heart. They may find they can’t repair the problem.

**Mrs. D:** They didn’t tell me that there was a possibility they may not be able to fix it. That is a risk.

**Nurse:** Yes it is. Then they also need to get you back awake and off the breathing machine, which may be difficult to do.

**Mrs. D:** So this is not an easy operation.

**Nurse:** No, it is not. And there are no guarantees.

**Mrs. D:** Oh my. I really need to reconsider all this. With what you are telling me, I could have the operation and still never get home.

**Nurse:** That is true.
Mrs. D.: And without the operation, I will never get home.

Nurse: That is correct. There is not a clear answer. Are there more things you have questions about?

Mrs. D.: No, I just want to think about this and talk it over later.

Nurse: Please feel free to write down any questions you think of, and I will come back later to answer anything else you need.

Often nurses understand that a patient is facing a choice but either does not understand all the information or is being given an unrealistic option. Here, the nurse realizes that the patient does not understand the complexities of the surgery and has unrealistic expectations that the surgery will cure her. She provides this information in accordance with Mrs. D’s information preferences.

Delivering Bad News

Bad or unfavorable medical news may be defined as "any news that drastically and negatively alters the patient's view of her or his future." 43 In palliative care, bad news includes, but is not limited to, disease diagnosis, recurrence, disease progression, lack of further curative treatments, transition to comfort care, and a terminal prognosis for a patient's condition. Nurses, particularly APNs, along with their physician colleagues, generally have the responsibility of communicating unfavorable news to a patient. The decision as to who delivers the news may depend on the relationship of the patient with the team, whom the patient trusts, as well as the APN’s scope of practice within the institution and state practice guidelines.

Two recent survey studies of oncology physicians conducted by Baile and colleagues are insightful. One study reported that 22% of oncology physicians had no consistent manner of communicating bad news, and 51.9% used several techniques or tactics without having an overall plan. 43 The second study revealed considerable variability in disclosing diagnoses and prognoses, reporting the absence of further curative treatments, discussing resuscitation, and making recommendations for hospice services. 44 There have been no such surveys among nurses, but, given the lack of education in this area, there is a high probability that the findings would be similar.

Coyle and Sculco beautifully described the emotional setting of giving bad news for the clinician and the patient (p. 212): 45

Is it possible for any news, transmitted by a doctor [or nurse] to a patient, to be “good news” in the face of advancing disease that is not responsive to chemotherapy? The doctor [or nurse] is in a position of having to give information that the patient does not want to hear, and yet the patient needs to have the information in order to make necessary life decisions. Does it matter how the information is given when medical information itself can remove hope for continued existence? . . . In a way, both parties—the doctor and the patient—are engaged in a communication dance of vulnerability. The physician is vulnerable because he/she must deliver the facts, whatever they may be, and the patient is vulnerable because he/she doesn’t want to hear any more bad news.

From Coyle and Sculco’s perspective, patients with advanced disease generally do want to have the information. Additionally, both physicians and nurses can be part of this communication dance. In a report by Yun and colleagues, 46 96% of 380 cancer patients and 76.9% of 280 family members stated that patients should be informed of a terminal illness. Not surprisingly, some discrepancy was apparent between the opinions of patients and those of family members regarding disclosure. Another study of cancer patients’ perspectives concluded that the most important factors when receiving bad news were the expertise of the physician and being given pertinent information about their condition and treatment options. Patients also rated other lesser, but still important, aspects of bad news delivery related to content, setting, and supportive aspects of the meetings. 48

It should be noted that, although patients may want to have the information, they may be reluctant to initiate such a discussion. 47 Moreover, patients may not be actively invited to express their feelings and concerns. One study showed that patients not provided with an opportunity to disclose concerns before the information is provided tended to remain silently preoccupied with the information and were more likely to develop a pessimistic sense of their situation, compared with patients who were invited to share and discuss their concerns. 47
CASE STUDY

PE, a Young Man with Metastatic Sarcoma

PE is a 20-year-old Spanish-speaking man with new diagnosis of metastatic sarcoma after having had back pain for 6 months. He was brought to the emergency department, where radiographs and computed tomography scans confirmed the diagnosis. A family meeting is called with a Spanish interpreter.

APN: P, I wanted to meet today to discuss your pain and your tests.

PE: (Quiet)

APN: Can you tell me how you are feeling?

PE: Okay.

APN: Are you having any pain?

PE: Some.

NURSE: How much, if 1 is none and 10 is the most pain you have ever had?

PE: A 3.

APN: And the cause of your pain, do you have any idea of that?

PE: Well I hurt my back and they couldn’t find anything.

APN: Well, do you remember that when you came here we did more tests? That was because the pain was worse.

PE: Yes.

APN: Well, I am afraid I have bad news about the tests.

PE: (Quiet)

APN: They do not look normal. We are having the experts on x-rays and the specialists look at them.

PE: (Still quiet)

APN: Can you tell me what you are thinking?

PE: My mind is cloudy right now. I am not thinking well. How can you be sure?

APN: We did several tests that showed a possible cancer in the pictures. In order to confirm the diagnosis, we would like to take a test of some of the tissue. Would you be okay with that?

PE: I want to be sure of the diagnosis, too. Cancer is bad. When would you do the test?

APN: Tomorrow. Is that okay? The results would take a couple of days. Then we could meet again with a cancer specialist to discuss these results.

PE: Yes.

APN: When we meet again, who would you want to be there?

PE: My family and my minister.

APN: Okay, we will do the test tomorrow and meet again in 3 days. I am hoping that perhaps I can give you better news. But I want to prepare you that it may still be bad news. In the meantime, other people are also available to be of support, such as our social worker. And we will continue to work on getting you more comfortable.

Here the nurse gives a warning shot of bad news but offers the follow-up meeting with test results and the specialist.

Behaviors used in presenting unfavorable information may be grouped into four domains: (1) preparation, (2) delivering the content of the message, (3) dealing with the responses of the patient (and family), and (4) closing the encounter. Critically important in the preparation for giving bad news is attention to one’s own emotional stress. This may include acknowledgment of possible feelings of guilt, lack of control, failure, loss, fear, or resentment. Awareness of these feeling can allow for a more objective encounter and clarity in ownership of issues. Nurses need to deal with their own sense of anxiety that results from empathizing with the patient.

Recommended guidelines have been developed for delivering unfavorable or bad news. Based on a review of the literature and a consensus panel of patients and physicians, Girgis and Sanson-Fisher recommended the following: (1) ensuring privacy and adequate time, (2) assessing patients’ understanding, (3) providing information about diagnosis and prognosis simply and honestly, (4) avoiding the use of euphemisms, (5) encouraging patients to express their feelings, (6) being empathetic, (7) giving a broad but realistic time frame regarding prognosis, and (8) arranging review or follow-up. Other points are summarized in Table 4–3.

Nurses perform a number of critically important functions when the patient is given bad news. First, the nurse may need to interpret, for the patient and the family, the medical information and jargon in a way that is understandable. Second, the nurse may need to restate information that the patient may not have heard due to the emotional impact of the bad news. Third, the nurse may need to investigate and support the patient’s emotional and psychological reactions to hearing the bad news.

In response to presenting bad news, patients may express comments or so-called dreaded questions, such as, “Why me?”, which many clinicians find very difficult to respond to. One approach is to maintain a sense of openness and curiosity and not to assume that one knows want the patient really means. An acknowledgment, such as “That is a tough question,” allows the nurse to comment and explore further without feeling the need to solve or “fix” the assumed source of the patient’s question or comment. This can be followed up by, “Please tell me what you are concerned about.” The nurse, by acknowledging and normalizing the patient’s feelings, invites the patient to voice his or her thoughts. It also reduces the patient’s sense of aloneness, and by sharing the patient’s distress, reduces suffering.

Another “dreaded question,” one that is particularly common when a patient has been informed of a terminal diagnosis or the lack of curative therapy, is the question, “How long do I have to live?” The nurse may choose to answer in several ways, depending on his or her comfort in these discussions. One response is, “How long do you think you have to live?” This allows the patient to voice his or her concern about time. The patient may say, “Not long, but I wanted to see how long you thought,” as if to compare input from different members of the team. Another response is, “Are you asking something specific?” Here the nurse is trying to ascertain whether the patient is asking about dying or is thinking of a certain event...
that he or she wishes to live to experience. A third response is, “Why do you ask?” This invites the patient to share his or her concerns about dying. Finally, if the anticipated survival time is short or the nurse is uncomfortable, the reply, “What has the team told you?” may be used. In this case, the patient may state that the team has given a certain estimate of time, or the patient may be seeking validation of the prediction.

Nonetheless, responding to and acknowledging such questions normalizes the discussion. It promotes further exploration of thoughts and feelings, resulting in reduced suffering through addressing of the patient’s fears and concerns. The nurse reflects on difficult information with, “I imagine it is very frightening not knowing what will happen and when. Do you have particular fears and concerns?”

### Table 4-3

<table>
<thead>
<tr>
<th>Main Teaching Points Regarding Delivering Bad News</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Create a physical setting consisting of a quiet, comfortable room with all participants sitting and free of interruptions.</td>
</tr>
<tr>
<td>2. Determine who should be present. Ask whom the patient wishes to have present and clarify the relationship to the patient. Clarify how much the patient wants to know. Decide whether other professionals (nurse, consultants, social worker, case manager, chaplain) should attend, and obtain patient/family permission.</td>
</tr>
<tr>
<td>3. Clarify and clearly state your goals and the patient’s goals for the meeting.</td>
</tr>
<tr>
<td>4. Be knowledgeable about the patient’s medical condition/illness, prognosis, and treatment options.</td>
</tr>
<tr>
<td>5. If the patient is not competent, arrange to have the legal decision-maker present.</td>
</tr>
<tr>
<td>6. If the patient or family does not speak English, use a skilled interpreter.</td>
</tr>
<tr>
<td>7. Determine what the patient and family know about the patient’s condition and what they have been told.</td>
</tr>
<tr>
<td>8. Provide a brief overview of the patient’s course and condition as a foundation for understanding for the entire group.</td>
</tr>
<tr>
<td>10. Give a warning: “Unfortunately, I have some bad news to share with you.” Others have suggested stating, “I wish things were different,” followed by a pause.</td>
</tr>
<tr>
<td>11. Present bad news in a concise and direct manner. Present information at the patient’s and family’s pace. Provide an initial overview. Assess understanding. Answer questions. Provide the next level of detail or repeat more general information in response to the patient’s and family’s needs. Provide truthful, hopeful statements, but avoid false assurances.</td>
</tr>
<tr>
<td>12. Sit quietly and allow the patient and family to absorb the information. Wait for the patient to respond. After being silent, check in with the patient such as by saying, “I have just told you some pretty serious news. Do you feel comfortable sharing your thoughts about this?” This may help the patient verbalize concerns.</td>
</tr>
<tr>
<td>13. Listen carefully and acknowledge the patient’s and family’s emotions, such as by reflecting on both the meaning and the affect of their responses. A study of patients’ perceptions to receiving bad news (about cancer) indicated the importance, to the patient, of a comfortable environment, adequate time for the meeting, attempts to empathize with the patient’s experiences.</td>
</tr>
<tr>
<td>14. Normalize and validate emotional responses, such as feeling numb, angry, sad, fearful. Using the pneumonic, NURSE (name, understand, respect, support, and explore), facilitate the sharing of emotions and reactions.</td>
</tr>
<tr>
<td>15. Give an opportunity for questions and comments.</td>
</tr>
<tr>
<td>17. Agree on a specific follow-up plan, such as a date and time for the next meeting, while inviting telephone contact in the interim. Treatment should be provided at the time of closure that meets the patient’s immediate needs, including treatment of any distressing symptoms. By the end of the meeting, the patient should feel supported. Conversation addressing aloneness and referral to other resources such as support groups, counselors, and pastoral care providers may help minimize a sense of isolation and abandonment.</td>
</tr>
</tbody>
</table>
After listening to the patient's and family members' fears and concerns, it is critically important to provide accurate, hopeful information while deliberately addressing the issue of nonabandonment. This can be done with such words as, "I wish things were different. But no matter what, I will be there to support you in your decisions and focus on your quality of life."

Advanced Care Planning

The American Nurses Association stated that nurses “have a responsibility to facilitate informed decision-making, including but not limited to advance directives. Studies have been performed of patients', families', physicians', and other caregivers' preferences regarding preparing for the end of life. All agree on the importance of (1) naming someone to make decisions, (2) knowing what to expect about one's physical condition, (3) having financial affairs in order, (4) having treatment preferences in writing, and (5) knowing that one's physician is comfortable talking about death and dying. Patients, more than others, want to have funeral plans made and to know the timing of death. Patients were less inclined to talk about personal fears than were families, physicians, and other caregivers. Identified as the most important factors in achieving quality at the end of life were the relief of pain and other distressing symptoms, communication with one's physician, preparation for death, and the opportunity to achieve a sense of completion. In spite of widespread agreement about the importance of preparation, such discussions often are not included in clinical encounters.

Both nurses and physicians perform advanced care planning discussions with patients and their families. Advanced care planning involves setting goals of therapy, developing advanced care directives, and making decisions about specific forms of medical therapy. For chronically ill, debilitated, and terminally ill patients, advanced care planning includes making decisions about life-sustaining therapies (code status), artificial feeding and hydration, and palliative and hospice care. Performing advanced care planning prepares for both incapacity and death, relieves burdens on others, solidifies relationships, and identifies appropriate surrogates and delineates their authority. For the terminally ill patient, the health care provider may begin the discussion about planning for the future by asking any of a number of questions, as described in Table 4–4.

Advanced care planning may be regarded differently depending on one's perspective. For the health care provider, advanced care planning prepares for the possibility that the patient may become incapable of making decisions. Advanced care planning is based on the ethical principle of autonomy and exercise of patient control, focuses on completing written advance directive forms, and occurs in the context of the provider–patient relationship. For the patient, advanced care planning may be regarded as a mechanism to prepare for death. Advanced care planning is a social process based on relationships and relief of burdens on others. It involves previous experience with poor health and death of family members, and it occurs in the context of relationships with close loved ones, not just with the health care system. As such, the nurse has a role in advocating the implementation of the patient's wishes.

Because survival estimates affect the decisions patients make, patients need accurate prognostic information. Interviews of 56 terminally ill patients concluded that all patients wanted their physicians to be honest about the prognoses conveyed. However, physicians often do poorly at estimating and reporting accurate survival times to patients. The patient's wish to hear optimistic information and the physician's reluctance to present information on disease progression may impair accurate portrayal of the patient's condition. Therefore, it is very helpful for nurses to be in attendance when such information is delivered. Nurses may then attempt to temper some of the overly optimistic survival times, given their knowledge from working with colleagues in various other professions. The disparity of the estimated survival times may confuse patients, particularly with other references such as the Internet readily available. Discussions between patients and providers about complementary treatments is essential to promote realistic outcomes.

Some of this information, including complementary and alternative treatments, may be inaccurate, harmful, or inapplicable when put in context of the patient's situation.

Advanced care planning discussions are best completed over time, allowing the patient opportunity for reflection and discussion with family and friends. The process of advanced care planning allows discussion about possible scenarios, which in

</tbody>
</table>
itself may prepare the patient for the course of disease. This includes potential circumstances of death and sharing of values. The result may be a sense of control, a sense of trust with health care providers, and a sense of resolution in aspects of one’s life. Patients tend to express their preferences for care after they understand their condition and options for therapy. Advanced care planning promotes the ability to evaluate such information in the context of the patient’s values and goals. A change in focus from future cure-oriented treatments to goals of current living may facilitate meaning and purpose.67 Having the patient consider such questions as, “What if we are not sure whether we will be able to get you off the breathing machine?” can help facilitate thought and decision about how much chance of success a patient needs to have to make certain decisions.68

Nurses at all levels provide important assistance in helping patients define their goals and wishes and express their cultural and religious practices and preferences. Nurses also help patients clarify both emotional reactions to their clinical situations and information about treatment options. Nurses play a critical role in advocating for the patient’s wishes and preferences and communicating these to family members and other health care providers.

Although patients may differ in the extent to which they wish to participate in treatment decisions, a number of studies have indicated preference to take a collaborative role. Being provided with adequate information is critical. However, simply being offered choices, particularly without any direction, can cause a patient to feel excessively burdened and responsible. The weight of these decisions can cause patients and families to feel a sense of self-blame or to lose confidence in the physician, particularly if the outcome is poor. Therefore, it is critically important to identify how much the patient wishes to be involved in decision-making at all stages of disease.69

It is widely agreed that discussions about advanced care planning and completion of advance directives should occur before acute, disabling events and hopefully before the end stage of a terminal illness. However, these conversations may not occur earlier, for a number of reasons: reluctance to initiate such discussions due to time constraints, lack of comfort with such discussions, lack of skills in such communications, and fear of upsetting the patient even though she or he may wish to have the conversation. A study of patients 50 years of age and older who had at least one chronic, morbid medical condition (ischemic heart disease, chronic heart failure, chronic obstructive pulmonary disease, cerebrovascular disease, cancer, chronic renal disease, or chronic liver disease) found that greater satisfaction with the primary care physician was expressed if advance directives were discussed during outpatient visits.70

Nurses may be particularly helpful in advocating for patients’ wishes and preferences when they are unable to speak for themselves. The nurse, working with the surrogate, may assist the surrogate to convey the patient’s wishes. If the surrogate is not certain about the patient’s wishes or if no advance directive is available, the nurse, by posing questions as those recommended by Harlow in “Family Letter Writing,”71 can be very helpful. Such questions include, “What type of person was the patient?” “Did she/he ever comment on another person’s situation when they were incapacitated or on life support?” “Did she/he relate those experiences to her/his own personal views of her/himself?” and “What vignettes can you recall from his/her life that illustrate her/his values?” In addition to helping to clarify a patient’s wishes, addressing these questions may also serve as a healing review of the person’s life and help identify what has brought them meaning. The nurse is often the best person to engage the family in such reflections and discussions as they have ample opportunity to talk during patient care.72

Communications About the Use of Life-Sustaining Therapies

One aspect of advanced care planning is often referred to as defining the code status of the patient. In the ideal collaborative process, nurses and physicians are jointly involved in these discussions. Nurses are heavily invested in clarification, because they often are the ones who find the patient in respiratory or cardiac arrest and must initiate a code. The nurse has a 24-hour presence with the patient, including bathing and being with the patient in the middle of the night and at off-hours; for this reason, the nurse may be the one to whom the patient and family turn for explanations and support. The nurse may be asked to explain what medical jargon such as “DNR/DNI” actually means, particularly in the context of the patient. The patient and family may also seek reassurance from the nurse about the appropriateness of their preferences and decisions or about pressure or responsibility they may feel concerning the way in which information was presented and the decisions they are being asked to make. Patients may very well ask the nurse, “Do you feel I made the right decision?” or “What would you do?” Patients may also need reassurance—for instance, that, by forgoing cardiopulmonary resuscitation (CPR), they are not denying themselves an intervention that could be beneficial. They may need reassurance that the nurses will continue to provide care. By educating the patient about the actual intervention and likely outcome, a nurse may be able to reassure the patient.72

“Code status” is commonly defined as the use, or limitation of use, of life-sustaining therapy in the event of clinical deterioration of respiratory function and/or cardiac arrest. Life-sustaining measures include nasotracheal intubation and mechanically assisted ventilation and cardiac resuscitation, the combination of which is called CPR. Other measures may include pressors to help the heart pump more efficiently and effectively, dialysis for kidney failure, and antibiotics for infections. If a patient in a hospital or nursing home or in the community experiences a cardiac arrest and/or respiratory failure and medical personnel are called to respond, CPR is performed unless the patient, or the patient’s surrogate, has indicated the patient’s desire not to be resuscitated (DNR) and/or not to be intubated and supported with mechanical ventilation (DNI).
When patient’s wishes for or against application of these medical interventions or treatments are being discussed and documented in the medical record, the process is often referred to as “getting the code status” or discussing “Do-Not-Resuscitate” orders.73

As in all other discussions with patients and their families about preferences for care, communications about code status should follow the same multiple-step process as described for communication on other topics of end-of-life care.9 In discussing a DNR order, Dr. Charles von Gunten74 recommended the steps of (1) establishing an appropriate setting, (2) inquiring of patient and family what they understand of the patient’s condition, (3) finding out what the patient expects for the future, (4) discussing the DNR order with the patient in the context of the patient’s understanding of present condition and thoughts of the future, including the context in which resuscitation would be considered, (5) responding to the patient’s emotions, and (6) developing a plan.74 Again, it is essential to place the conversation in the context of the patient’s wishes for goals of therapy.

In developing appropriate goals of care for the patient’s condition, the patient or health care proxy must understand the very low likelihood of survival after CPR in the presence of terminal illness.75 Patients are less likely to opt for CPR knowing that almost no patients with severe, multiple, chronic illnesses who receive CPR in hospital survive to discharge.68,76

For nurses to discuss code status, there are several issues. First, just discussing code status in and of itself is worthless. Alone, a code status guides the health care team in deciding whether or not to perform a procedure. Use of medical vernacular, such as “full code” or “no code” and “Do you want everything done?” is ambiguous at best, and offers little guidance. Use of language that the patient understands and review of the broad topic of life-sustaining treatments can guide the health care team to a better understanding of the patient’s values and preferences such as, “Mr. X, you told me you want to be comfortable and not return to the hospital. We can get support at home to keep you comfortable and aggressively treat any symptoms.” Important elements of this discussion include sensitivity to, acknowledgment of, and response to emotions of the patient, family, and surrogate.

Sometimes, the responsibility of making such a decision is too great for patients and families. They may feel that by making a choice to refuse resuscitation, they are “pulling the plug.” In these situations, the nurse can offer a plan and then ask for agreement from the patient and family. By saying, “We would like to focus on comfort and maximal pain and symptom management. That would include medications to treat symptoms with nurses to manage these medications. We will not do any procedures that would cause more pain than benefit. And because we anticipate your decline, we will try to keep you home with hospice and not to do anything to prolong your dying. Is that okay?” It may still be the same plan, but the family doesn’t have to make the decision. The burden of the decision is removed from the family and placed on the care team, but the patient and family agree to the plan.

To dispel concerns of abandonment, it is particularly important to reassure the patient, family, and surrogate that even though CPR will not be performed, all beneficial care will be actively provided. The final task is to develop and document a plan and share this information with other health care professionals caring for the patient.77 This may be done through documenting the conversation and completing state-recognized comfort care/DNR order forms.

### Conversations About Artificial Hydration and Nutrition

Decisions about resuscitation are just one of the many decisions that patients and families need to make regarding end-of-life care. Both nurses and physicians discuss specific treatment options and develop a plan of care with the patient, but it is

**Normalizing comments/questions:**

I’d like to talk with you about possible health care decisions in the future.

I’d like to discuss something I discuss with all patients admitted to the hospital.

**Inquiries of patient’s understanding:**

What do you understand about your current health situation?

What do you understand from what the doctors have told you?

**Inquiries to elicit hopes and expectations:**

What do you expect in the future?

Have you ever thought about how you want things to be if you were much more ill?

**Inquiries to elicit thoughts regarding cardiopulmonary resuscitation:**

If you should die despite all our efforts, do you want us to use “heroic measures” to bring you back?

How do you want things to be when you die?

If you were to die unexpectedly, would you want us to try to bring you back?
often the nurse who facilitates a peaceful death\textsuperscript{79} by talking with the patient about his or her goals, wishes, and preferences; being cognizant of the patient’s suffering; and conveying this information to other health care providers.

When patients are not able to take food or fluid by mouth, artificial hydration and nutrition may be provided through the gastrointestinal tract with a nasogastric or gastric tube or intravenously. The rationale for and against these procedures is discussed in the Chapter 12. The discussion points regarding artificial hydration and nutrition with the patient and/or the patient’s surrogate include (1) their perception of the benefits and the suffering with or without these interventions; (2) the values, beliefs, and culture of the patient and family along with the goals; (3) the available data regarding the benefits and burdens of the interventions; and (4) collaborative decision-making about these interventions to meet the patient’s goals.

Many cultures place great social and cultural importance on drinking and eating. Many people believe that not eating and drinking causes great physical suffering. Therefore, it is necessary to discuss the potential benefits and burdens of instituting artificial hydration and nutrition, as well as the benefits and burdens of withholding artificial hydration and nutrition. Nurses can stress ways of maintaining social contact associated with eating and drinking. A speech and language pathologist or a swallowing therapist can assist in promoting maximal safe and appropriate intake. If the patient is unable to take any food or fluid by mouth, providing human contact on a regular basis, similar to that while feeding, may address this concern. The concern of “suffering” or of “starving the patient to death” may be minimized by education regarding this concern. The concern of “suffering” or of “starving the patient to death” may be minimized by education regarding this concern.

When patients are not able to take food or fluid by mouth, artificial hydration and nutrition may be provided through the gastrointestinal tract with a nasogastric or gastric tube or intravenously. The rationale for and against these procedures is discussed in the Chapter 12. The discussion points regarding artificial hydration and nutrition with the patient and/or the patient’s surrogate include (1) their perception of the benefits and the suffering with or without these interventions; (2) the values, beliefs, and culture of the patient and family along with the goals; (3) the available data regarding the benefits and burdens of the interventions; and (4) collaborative decision-making about these interventions to meet the patient’s goals.

The risks and burdens of artificial hydration and nutrition include lung congestion and increased respiratory tract secretions, increased edema with its attendant pain at sites of tumors and inflammation, more urine production, more peripheral swelling (particularly in the setting of liver or kidney disease), and skin breakdown. Feeding tubes and intravenous lines may be painful, carry risks of infections, and may be fraught with complications. These may include restraint of the patient to prevent removal, which can cause secondary agitation and may also result in accelerated skin breakdown from less turning in bed. Ultimately, the use or avoidance of such interventions as artificial hydration and/or nutrition depends on the patient’s goals of care.\textsuperscript{73–82}

**Conversations about the Transition to Palliative Care or Hospice**

The hospice and palliative care movement has promoted discussions of the benefits and burdens of medical interventions. The patient and family are helped to prepare for death in as comfortable and meaningful a way as possible by focusing on various physical, psychological, and spiritual aspects of care.\textsuperscript{73,83,84} The nurse has a central role in palliative and hospice care by implementing the plan of care. The APN may assist the patient in this transition and develop orders for the treatment plan. The nurse, together with the interdisciplinary health care team, empowers family and friends to support and care for the patient. The constant presence of the nurse reassures patients and families that abandonment is not an issue.

The transition from curative to palliative care is often a challenge for clinicians, patients, and families alike. It signals the recognition of loss from various perspectives. Patients may feel a sense of sadness, anger, denial, and loss of control. Physicians may feel a sense of failure for not curing the disease, a lack of confidence in not knowing what else they can do for the patient, and perhaps worry about their own personal reactions as well as patients’ emotions.\textsuperscript{48} Nurses may be frustrated if a patient is not well informed to accomplish life closure. Moreover, nurses involved in direct bedside care may dread the possibility of having to provide resuscitation measures in such a circumstance. Nurses may dread situations in which the primary physician, who knows the patient, is not available, and the nurse must deal with a covering physician who may employ inappropriately aggressive and burdensome interventions because he or she has not been involved in the patient’s care and does not know the patient and the family.

As in other end-of-life conversations, talking about the transition to palliative care or hospice care should be guided by the patient’s overall goals. As previously explained, these goals are stated in terms of the relative value of prolonging life compared with focusing on quality of life and comfort. In addition to advance directives, health care proxy documentation and living wills, resuscitation orders (code status), and use of other life-sustaining therapies, other important facets of end-of-life discussions include use of antibiotic therapy; use of hemodialysis; management of pain and other distressing symptoms; relief of psychological, emotional, spiritual, and existential suffering; completion of unfinished business; and anticipatory grief.\textsuperscript{27}

Strategies recommended by Larson and Tobin\textsuperscript{85} for initiating end-of-life conversations during the last phase of life include (1) focusing on the patients’ unique experiences of illness, (2) helping patients confront their fears, (3) helping patients address practical issues, (4) facilitating the shift to palliative care, and (5) helping the patient achieve a peaceful and dignified death. This means that each situation is individual and cannot be determined by an algorithm or recipe approach. To facilitate such end-of-life discussions, which focus on the realities of advancing illness and changing treatment goals, Larson and Tobin propose specific questions and comments, which are listed in Table 4–6.

After the patient has been referred to palliative care, the nurse may reinforce the reason for end-of-life care and the involvement of new specialized health care providers. The focus on quality of life continues in its multidimensionality determined by the patient. Both patients and physicians display reluctance to discuss psychosocial issues unless the other party initiates the discussion.\textsuperscript{36} It behooves nurses, along with social work colleagues, to initiate such conversations, because the evidence suggests that little time is devoted to quality-of-life issues.
during outpatient palliative care visits. Table 4–7 lists open-ended questions that may help facilitate quality-of-life discussions with patients.

Von Gunten recommended a step-wise approach of establishing the setting, eliciting the patients’ understanding of their condition and their expectations for the future, discussing what hospice care is, responding to emotions, and developing a plan. Conducting a family meeting to respond to patient and family concerns, to discuss the patient’s wishes with other family members and health care professionals, to have the hospice team provide information, and to collaboratively develop a plan may serve to help communicate what hospice care is.

A number of strategies may be used to address feelings of powerlessness, uncertainty, isolation, and helplessness that otherwise could lead to a sense of hopelessness in the patient. These strategies include explaining what to expect regarding the patient’s decline and the patient’s involvement in decision-making, as well as encouraging relationships and connections with important people. Such discussions lend themselves to strategies for life closure in identifying patient goals and purposes, preparation for death, leaving a legacy for loved ones, and often legal and financial issues. Completing these tasks frees the patient to concentrate on emotional and spiritual matters and to enjoy the company of loved ones.

Communications as the Patient Is Dying

When curing is no longer viable and this message is communicated to or intuitied by the patient, a pregnant moment for healing arises for both physician and patient. The focus and fight for life can give way to a new alliance based on sharing the inevitability of the human contract. The smallest, most humble act of a change to more generic reaching out can have exponential benefit to the patient’s subjective sense of well-being.

Nurses’ communications with the patient and family, when death becomes inevitable, may facilitate comfort and healing in a number of ways. Using patient wishes to review treatment options, advanced care planning issues, and use of life-sustaining measures, nurses can promote comfort in a patient’s final days. Treatment issues include pain management while respecting a patient’s preferences for pain alleviation versus desired level of alertness, and addressing eating, drinking, and artificial hydration and nutrition. The nurse should review the actual physiological and biological process of dying in language that also addresses the benefits and burdens of various interventions. This includes discussions with the patient, family, and other health care professionals about withdrawing ineffective and/or burdensome medical treatments that may not yet have been discontinued. Simple presence, listening, and attending to the basic humanity of the dying patient may be one of the nurse’s most powerful contributions.

The simple act of visitation, of presence, of taking the trouble to witness the patient’s process can be in itself

a potent healing affirmation—a sacramental gesture received by the dying person who may be feeling helpless, diminished, and fearful that they have little to offer others. The patient may also fear that he or she has failed. . . . I and many dying persons would agree that beyond pain control, the three elements we most need are feeling cared about, being respected, and enjoying a sense of continuity, be it in relationships or in terms of spiritual awareness.91

The communication skills required include being present with the patient in his or her state of vulnerability and decline, and consciously and nonjudgmentally listening and bearing witness to the patient, encouraging the patient to express all feelings while resisting defensiveness if the patient voices anger or disappointment about dying.

The willingness to extend to the patient with freshness, innocence, and sincere concern far outweighs any technique or expertise in the art of listening. Practice and exposure hone these skills and deepen one’s personal awareness, which in itself is the fertile soil for end-of-life completion work for both parties.91

Nurses, by communicating physical and behavioral signs of the dying process, may help prepare patients and families and thereby reduce anxiety and ease the bereavement process. Nurses, in response to patients’ desires to appreciate the purpose and meaning in their lives as they face death, may use interventions to help relieve spiritual suffering. Being present with the patient and encouraging a life review by recalling and talking about memories and past conflicts may help patients and loved ones to recognize purpose, value, and meaning. Performing a life review also helps patients achieve resolution of past conflicts, forgiveness, reconciliation, a sense of personal integration, and inner peace. Goals may be reframed into short-term activities that can be accomplished. Meditation, guided imagery, music, reading, and art that focuses on healing may be comforting.24

Role modeling the art of being present to the dying person for families is important. Engaging in loving, physical contact, such as holding hands, embracing, or lying next to the patient, may help the patient in his or her transition and may help the survivors in their anticipatory grieving. For families who want to be present at the time of death, explaining that patients often wait until they are alone to die may prevent the family from feeling a sense of guilt if they are away from the patient at the time of death. Allowing the family to be with the patient after death may help the surviving family members grieve the loss of their loved one.

Nurses’ awareness of anticipatory grief and bereavement and communications with family members and other loved ones may help them through these painful times. Bereaved families are often in most need of having someone to listen to them. One of the nurses’ most important roles in working with grieving patients and bereaved families is active, compassionate listening. Encouraging the bereaved to tell stories of their loss, including details of the days and weeks around the death of their loved one; encouraging the sharing of memories of the person; asking about how things are different now; and helping to identify sources of support, of coping, and of accomplishing practical daily activities may be of great assistance.92

Family Communication

In 1995, Zerwekh93 suggested a family hospice caregiving model whereby communication, in particular the nurse’s communication, sets the tone for all care. In this model, the role of the nurse is to help guide the care. Speaking the truth enables the nurse to connect with family members and empower them to make choices, but also to be collaborative, to comfort, to guide the dying process, and to provide spiritual support.

Nurses, by the nature of their practice, understand that the focus of care is on patients and their families. Because the essence of nursing is to care for actual and potential health problems of the patient and family, the scope of care is broad. Challenges arise when the patient and the family are in conflict. In these times of nursing shortages, interference from family members at the bedside may overwhelm the nurse in her best efforts to provide care for the patient.

Within the spectrum of the patient’s illness, the family has various communication needs. First of all, because of caregiving demands, family members feel a part of the illness.95 Therefore, they want to be included in any communication pertaining to disease progression, treatment options, and goals of care. Additionally, family members, because of their knowledge of the patient, may serve as the best advocates for their ill family member.19 This is well illustrated in pediatrics, where parents are considered to be the experts on their children. Family members carry the burden of caregiving—an exhausting task that may include scheduling appointments related to care, arranging transportation for these appointments, attending to the ill person, and providing direct care.19

One challenge for the nurse is to decipher the patient’s important relationships and determine who should get what information. Another challenge is to help family members with the issues of caregiving. The very logistics of caregiving can be overwhelming with respect to demands of time and energy. Families need assistance in rallying support to care for loved ones and to identify and access community services. Additionally, families need support in dealing with the emotional burden of caring for the loved one alone while at the same time dealing with other aspects of their own lives, demands that may include a full or part-time job and financial stresses. For some families, it may be necessary to continue working in order to maintain insurance coverage. Families may need to hire extra help that is considered custodial and is not covered by insurance. Moreover, lack of education about providing direct care may create a tremendous sense of inadequacy in the caregiver. Families often need education in aspects of physical caregiving, including transfers and personal care.94
Moreover, there may be a number of challenges within the family itself related to family functioning, coping strategies, and processes of communication. In an attempt to negotiate the health care system and advocate for a loved one, a family member can intentionally or unintentionally create havoc by rejecting assistance or accepting too much help. In an attempt to seek a cure at all costs, too many health care providers may be consulted for a case. This can be a set-up for failure due to splitting or absence of a lead person to make decisions. Family members, intentionally or unintentionally, may work at cross-purposes or cause health team members to work at cross-purposes. This may serve to undermine care and to prevent addressing important aspects of terminal care. However, there may be clear informational issues that need to be addressed. To successfully ascertain the situation, the nurse needs to know about the communication style of the family. Duhamel and Dupuis offered the following questions:

What is helping you the most?  
Where are you getting support?  
What information do you need right now?

Other challenges for the nurse are a mismatch of patient and family needs for information and communication and differences in coping styles. A patient may need little communication, whereas certain family members may need constant updates, partially because they are unable to attend appointments with the patient. In other settings, a patient may have a need to communicate but the family member is comfortable being quiet. Being at different places in coping may also create tension between a patient and his or her family. A patient may be coping well and adjusting to the physical changes, whereas a family member may just be beginning to deal with the diagnosis of a life-threatening illness and not be able to even conceptualize a prognosis. On the other hand, a patient may be too overwhelmed by symptoms to deal with psychological aspects of care, whereas a family member may be more objective.

To best work with families, the nurse can use several strategies. First, frequent interaction with family members can help the family feel included and not avoided. Second, understanding of the family’s communication styles can help in these interactions. As part of the nursing assessment, a determination of the family’s understanding of the patient’s condition helps facilitate communication. In collaboration with the patient, the nurse can clarify the family’s roles and responsibilities and support their efforts and sacrifices as caregivers. This is critically important when working in partnership with patients and their families. The nurse may also be of great assistance to the family in helping them with anticipatory grieving and bereavement. Eliciting the coping mechanisms of the patient and family is an important part of patient assessment, as the patient transitions in care and later progresses to dying, and also of family assessment during these times and during bereavement. Particular questions may help clinicians and other members of the palliative care and hospice teams address and support patients’ and families’ coping mechanisms (Table 4–8).

Communication with family members is as important as communication with the patient. The family may not understand as much as the patient does, or the family may understand more than the patient. The family’s questions and comments may focus on their coping and coming to terms with the patient’s potential death. Sometimes, a nurse needs to interact with many family members, which can be exhausting and can ultimately require one family member to serve as the spokesperson. This work is very labor intensive, because different family members have varying needs for information and reassurance. Nevertheless, this communication is essential, because the nurse may coach the family as to how to communicate effectively and compassionately with the patient.

**CASE STUDY**  
Mr. T, an Elderly Man with Complications After a Fall

Mr. T is an 85-year-old man who was living without family and was fiercely independent. One day, he fell down the flight of stairs in his house. He crawled back up to bed. Three days later, he tried to move and could not. He called 911 and was brought to the hospital by emergency responders. There he underwent spinal cord surgery and then spinal fusion. During his recovery from surgery, he suffered a stroke. He was treated with heparin and then suffered an intracranial bleed. He is now limited to movement in only his left upper extremity. Mr. T is awake and alert, but is nonverbal and does not follow commands. His sister, Mrs. O, is distraught over his care. A meeting is held with the neurosurgeon and the palliative care nurse.

**Nurse:** Mrs. O, I am the palliative care nurse. I was asked by Dr. Q and Dr. P to help out with your brother’s care. We decided it would be best to meet with you together to figure out a plan of care.

**Mrs. O:** Dr. P, please tell me if my brother will get better.
DR. P: Well your brother suffered major injury to the spine when he fell. He was brought here, and we tried to fix his spinal cord so that he would be able to move. We were somewhat successful in giving him a little movement. However, then he suffered a stroke. The neurologists have treated him and believe that this is the best he will get. As you can see, he is alert and awake.

MRS. O: But he doesn’t seem to understand anything and he can’t talk to me.

DR. P: Well, he seems to enjoy watching TV and could do well with some rehabilitation. However, he will probably never be able to live alone again.

MRS. O: What do you expect from rehabilitation?

DR. P: He may gain a little strength and some vocalization. But he will never be able to move more than his arm.

MRS. O: So this is the best he will get?

DR. P: Yes, we managed to save him. Although, he won’t be able to do much, he can get satisfaction from being with people and watching TV.

MRS. O: But he was very independent and never wanted any help. In addition, he always told me he would never want to go into a nursing home. He thought that was a horrible way to live, and he said it every time we passed a nursing home.

DR. P: But he could still get a little better with some rehabilitation.

MRS. O: For what, to be like that? That is no quality of life. What choices does he have?

DR. P: Well, if you don’t want rehabilitation for him, you could have the palliative care service start a morphine drip. (He then leaves)

MRS. O: Is that what you do?

NURSE: No, we focus on the preferences of the patient and the family. Tell me about your brother and what he was like.

MRS. O: Well he lived alone all his life. He loved my sons like his own. He taught them woodworking. They would go up and see him once a week to check up on him and make sure he had enough food. We asked him to live with us, but he would have none of it.

NURSE: What are your thoughts about his care?

MRS. O: He would never want to be like this. If he could look at himself, he would die from embarrassment. He hated TV. Having only the quality of life to watch TV would be awful for him. He was a doer. He never sat for long.

NURSE: So you are thinking this would not be the type of life he would want?

MRS. O: No. It seems like getting him rehabilitation would serve no purpose. But I don’t want to kill him. You wouldn’t do that, would you?

NURSE: No, we only treat a patient’s symptoms. He does not seem to have any physical pain or distress.

MRS. O: Then I just have to wait for him to die? Where will he go?

NURSE: No, there are some considerations about his treatment you can make. First of all, he has been in bed a long time. He is deconditioned and he could get pneumonia. You can decide not to treat that.

MRS. O: I can?

NURSE: Yes. You can also decide that if he has any other events, such as if his heart or his breathing stops, he would not undergo shock to restart his heart or be put on a breathing machine.

MRS. O: I definitely don’t want him put on any machines to keep him alive.

NURSE: You can also decide that you don’t want to give him artificial nutrition and hydration. Instead, he can eat what he can with the assistance of other people. And we could keep his mouth and lips moist so he doesn’t feel thirsty. He could still taste food, but we would let him enjoy eating while knowing he may get pneumonia. Is that something you would consider?

MRS. O: Yes. My brother would have hated all this. I just want to let nature take its course, but not see him suffer.

NURSE: Then we will not do any aggressive life-prolonging treatment. Instead, we will focus on his comfort and quality of life. Only if he seems uncomfortable—is restless, agitated, or in pain—would we use medicines to help him be comfortable. Does that seem like the right plan for him?

MRS. O: Oh yes. Thank you so much. My brother would be so relieved to know all this. I just can’t go against his character.

Here the nurse allows the family member to describe her loved one. This facilitates the decision-making by the sister on her brother’s behalf.

Often, family communication is best done within a family meeting, a wonderful but greatly underutilized tool. Most clinicians, with the exception of social workers, have not been taught how to effectively run a family meeting. Family meetings help the family understand the involvement of various health care providers, the disease process, and options of care. They also reassure families that a plan is in place and everyone is working toward a consistent goal. The family meeting also provides clinicians an opportunity to collaboratively formulate a plan of care that is consistent with the goals and wishes of the patient and family.

Before calling a family meeting, it is important to clarify the goal for the meeting, to maximize the effective use of time. This can range simply from an update of care to discussing withdrawal of technological interventions. Consideration should be given to the attendance of key and central health care providers, who should meet at least a few minutes before the meeting to clarify the messages to be conveyed. For more complex or contentious families, having a meeting specifically to plan strategies to deal with a difficult family is time well spent.

The actual family meeting is fairly easy and is based on common sense. The patient may or may not attend depending
on his or her condition, decision-making capacity, and preference for involvement. One person should take the lead, ensuring that everyone in the room is introduced, and review of the goal of the meeting. Often the family has not met various providers, even if the patient has, and not all health care providers know each other. At that point, depending on what the team has decided ahead of time, another person may ask for the family’s understanding of the patient’s current condition. This speaker may offer a summary of the care. The next part of the meeting addresses questions and issues that require clarification. It is helpful to have the health care team present to hear the concerns and clarify issues in their areas of expertise. After this discussion, the lead person can summarize the issues and collaboratively develop a plan of care. If the family agrees to the plan, the meeting can end with a synopsis of the meeting and the decisions made. If the family disagrees, another meeting can be suggested. One of the most important tasks after the meeting is documentation. The names and titles of the people who attended, the issues discussed, and the decisions made should be documented in the medical record, as outlined in Table 4–9.

**Team Communication**

It is commonly agreed that palliative care is best delivered in an interdisciplinary fashion. The underlying reasoning is that well-functioning interdisciplinary teams can share responsibility for care, are able to balance multiple perspectives in care, can support each other in the provision of care, and can provide more comprehensive care, compared with a sole individual clinician. Good teams promote the establishment of effective communication, cooperation, and competence. The essential elements that make effective and efficient teams include coordination of services, shared responsibility, and, not surprisingly, good communication.

The diversity that gives the interdisciplinary team its effectiveness is dependent on good communication among its members. Witnessing good communication among health care professionals is also reassuring to patients and their families.

Nurses must work closely with physicians at various levels, depending on their role and practice. Nurses find that working in different environments dictate interactions with physicians that may be characterized by deference or by true collaboration. Communication skills with colleagues vary from those used with patients; mutual respect and understanding, rather than hierarchy, lead to the best results. However, nurses and physicians may differ in their communication styles. Whereas physicians often want facts and numbers, nurses often emphasize process, leading to conflict in communication styles. It is best if nurses are clear about the purpose of any communication, and it is important for them to have the appropriate supporting evidence. If the contact is about information sharing, the nurse should be brief. If a treatment change is warranted, the nurse should have the supporting evidence. For example, if calling about pain and symptoms, the nurse should know the medications the patient is taking, when they were last taken, and the patient’s pain scores, and should offer a suggested plan. Without this information, it can be frustrating for physicians to offer any treatment changes.

A struggle often occurs because much of palliative care is care that nurses have historically provided. Indeed, the central caregiver in hospice is the nurse. In palliative care, the more academic aspect of end-of-life care, physicians now are taking on many aspects of the nursing role. Because of the interdependence of the members of the team, interdisciplinary roles may become blurred. This can result in a favorable collaboration, but it may also result in tension and competition among members of the interprofessional team. Tension may exist due to the fact that much of palliative care is still the 24-hour care provided by the bedside nurse. Therefore, it is important to work out the conflicts and to recognize the role of each team member in the care of the patient.

Understandably, there can be some darker sides of team interactions. According to Kane, stress and tension can arise from ethical conflicts among team members and conflicting goals regarding patient care. Eight problems may occur within a team: (1) overwhelming the patient, (2) making the patient part of the team, (3) squelching of individual team members, (4) lack of accountability, (5) team process trumping client outcome, (6) orthodoxy and groupthink, (7) overemphasis on health and safety goals, and (8) squandering of resources. All of these issues can occur at various times within the palliative care team and necessitate good communication and conflict resolution. Examples of these problems include the following:

1. Overwhelming the patient—This occurs often at a family meeting, where there may be the patient, one family member, and many health care professionals. The patient or family may feel outnumbered and hesitant to talk about the goals of care.
2. Making the client part of the team—Patients are told that they are part of the decision-making team and are asked for input. However, the fact is that patients who are dying may not have the energy to advocate for themselves. Rather, they want other people to advocate for them.
3. Squelching of individual team members—The team may explicitly say that everyone’s input is equal when implicitly that is not the case. Nonphysician voices may be dismissed. The nurse must often work hard to be heard.
4. Lack of accountability—This is often a challenge when there is a primary team working with other consultants such as palliative care teams. The team is consulted to do a certain thing. There can be tension if they see other things that should be done but they have not been asked to address these issues.
5. Team process trumping client outcome—Often, in providing end-of-life care, health care providers have certain ideas or feelings about what is right or wrong. The challenge is to allow an open process to occur and not to limit it to one particular pathway simply because that is the way it is always done.
6. Orthodoxy and groupthink—A group can become insular and not incorporate new ideas. The team becomes unable to assess itself, and obvious problems are overlooked. In end-of-life situations, this often happens in relation to the dying process. Nurses may see that the patient is dying, but other health professionals look for a specific symptom and treat it. The fact that the patient is dying is overlooked.
7. Overemphasis on health and safety goals—The care plan takes over, in preference to the patient’s needs.
8. Squandering of resources—Needs of patients are missed, and high-cost interventions are implemented.

In summary, interdisciplinary teams have much to offer patients and families. Together, the various disciplines can meet the needs of the whole person. However, teams have their own dynamics, just as a family does, because they are, in effect, social systems. With good leadership, role delineation, and flexibility, interdisciplinary teams work well, creating a synergy that promotes positive outcomes. There are inherent issues that may make teams less helpful if they do not take the time to reflect on their process. To look at its effectiveness, a team needs to assess its process. First, the participation of all members is essential; the degree of involvement may depend on the issues of the patient and family. Second, each team member should have a voice in the process. Third, the mission and goals should be a periodically reviewed so that all members are working on the same premise. Finally, each team member should understand his or her role in patient care and maintain the process of the group. With a periodic review of these issues, the group will work more effectively and efficiently as a team. Reflection helps a team mature, avoiding some of the pitfalls of teamwork.

Conflict Resolution

Conflict is a situation in which the concerns of two or more people or parties appear to clash. This may occur between a patient and a nurse, between a nurse and a doctor, or between two health care teams. Conflict is inevitable and healthy. If managed well, it helps people look at different perspectives and can allow for creativity and positive movement. If dismissed or ignored, it can breed decreased productivity, decreased quality and commitment, and negativity. Nurses on the front line deal with conflict all the time. The challenge is to recognize the conflict and the nature of the conflict. Often, two teams have different ideas, and the nurse is caught in the middle. In this situation, it is best if the nurse expresses the need for the teams to talk to each other. Sometimes, patients and families split staff. Here it is best if the team speaks with consistency and frequency.

There are several methods to resolve conflict between team members, or between a colleague and a patient. The two extremes are conflict avoidance and continued conflict. Between the extremes on this spectrum are negotiation, accommodation, and collaboration. What differentiates these processes is the perceived power differences. Nurses, depending on their level of practice, practice site, and experience, may deal with conflict differently. Even within nursing, there may be tension between generalists and APNs. Historically, an imbalance of power has existed between attending physicians and nurses. However, with social work colleagues, nurses have felt equal, with a balanced or similar power. Often, nurses avoid conflict if they constantly have difficulty dealing with a team member who will not talk about disagreements. However, in palliative care, the goal should be collaboration in which all problems are discussed and mutual solutions are reached.
order to best solve conflict, there are several strategies. Common issues of team conflict include information, common goals, values, role expectations, and differences in underlying values.101

Conflict resolution occurs through a process (Table 4–10). First, the nurse identifies the source of the conflict. This includes reviewing the conflict in terms of what happened, what the impact was, and what emotions contributed to the conflict. Second, the nurse reflects on the goal of conflict resolution in terms of what she or he hopes to accomplish. Then the nurse addresses the conflict. In doing so, the two parties share their common purposes and differing interests. This leads to exploration of the conflict and letting each party tell his or her perspective while acknowledging feelings and each party’s version of the events. Finally, the two parties problem solve and decide on a tack of resolution.109,110

Achieving Expertise in Communication

Achieving expertise in communication requires a long-term commitment. First, a nurse must assess her own strengths and weaknesses in communication, and specifically in the area of death and dying. Completing a death awareness questionnaire helps identify areas of comfort and discomfort regarding discussions of death and dying. Often, it is helpful for the nurse to ask colleagues to observe how he or she talks with patients and to give honest feedback. It may also be helpful to spend some time with hospice and palliative nurses who can discuss more about the communication process. Reflection of a nurse’s own areas of strength and style of communication is helpful, because language and words are individual to one’s experience and practice. It is also helpful to have a place to develop and acquire skills. This may occur in a formal preceptorship, formal education, or mentoring with expert nurse colleagues. Sometimes, this can be done by writing a narrative about a difficult case, doing a case review, or participating in peer supervision of all cases of patients with life-threatening illnesses.

Conclusion

Communication is the cornerstone of end-of-life care. Good communication sets the trust and the tone for all aspects of care. Effective communication allows patients to paint a picture of themselves and their priorities, values, and needs in the last stages of life. Communication facilitates the expression of feelings by the patient and family members, including their sense of issues and problems surrounding a life-threatening disease and their concerns about care.

Properly developed and used, communication holds all the essentials of end-of-life care together. If it is improperly used, the care and care plan of the patient can fall apart. Nurses, by the virtue of their close proximity to patients, have the potential to participate in myriad communications with their patients. It is incumbent on nurses to acquire the skills necessary to make their communications effective.

Pain Assessment

Pain—has an Element of Blank—
It cannot recollect
When it began—or if there were
A time when it was not—

It has no Future—but itself—
Its Infinite realms contain
Its Past—enlightened to perceive
New Periods—of Pain.

—Emily Dickinson, 1955

• Key Points
  • Pain is multifactorial and affects the whole person.
  • Pain prevalence at the end of life is high and can be acute, chronic, or both.
  • Patients or residents should be asked whether they have pain (screened for pain) on admission to a hospital, clinic, nursing home, hospice, or home care agency.
  • If pain or discomfort is reported, a comprehensive pain assessment should be performed at regular intervals, whenever there is a change in the pain, after analgesic administration, and after any modifications in the pain management plan.
  • The patient’s self-report of pain is the gold standard, even for those patients who are nonverbal or cognitively impaired.
  • Standard pain scales should be used in combination with clinical observation and information from health care professionals and family caregivers.
  • Multiple barriers to pain assessment exist.

Pain is a common companion of birth, growth, death, and illness; it is intertwined intimately with the very nature of human existence. Most pain can be palliated, and patients can be relatively pain free. To successfully relieve pain and suffering, accurate and continuous pain assessment is mandatory. However, evidence demonstrates that pain is undertreated in the palliative care setting, contributing significantly to patient discomfort and suffering at the end of life. Studies suggest that as many as 30% of newly diagnosed cancer patients, 40% of those undergoing treatment, and 75% of those in the terminal phase of disease have unrelieved pain.\(^1\) One study reported that more than 50% of cancer patients have increased suffering requiring sedation in the last days of life.\(^2\)–\(^9\) Coyle and colleagues\(^10\) reported that 100% of their patients had pain and 37% had increased opioid requirements of 25% or more during the last month of life. In the Palliative Care Consultation Service at the Medical College of Wisconsin, pain and end-of-life decisions were the most frequent reasons for consultation.\(^11\) Although nursing homes are increasingly becoming the most common site of death for the elderly,\(^12\)–\(^13\) pain relief in long-term care facilities varies widely, with 45% to 80% of residents having substantial pain with suboptimal pain management.\(^14\)–\(^20\)

This chapter considers various types of pain, describes barriers to optimal pain assessment, and reviews current clinical practice guidelines for the assessment of pain in the palliative care setting. A multifactorial model for pain assessment is proposed, and a variety of instruments and methods that can be used to assess pain in patients at the end of life are discussed.

Types of Pain

According to the International Association for the Study of Pain (IASP), pain is defined as “an unpleasant sensory or emotional experience associated with tissue damage. The inability
to communicate verbally does not negate the possibility that an individual is experiencing pain and is in need of appropriate pain-relieving treatment.21 Pain has also been clinically defined as “whatever the experiencing person says it is, existing whenever the experiencing person says it does.”22

Pain is commonly described in terms of categorization along a continuum of duration. Acute pain is usually associated with tissue damage, inflammation, a disease process that is relatively brief, or a surgical procedure. Regardless of its intensity, acute pain is of relatively brief duration: hours, days, weeks, or a few months.23 Acute pain serves as a warning that something is wrong and is generally viewed as a time-limited experience. In contrast, chronic or persistent pain worsens and intensifies with the passage of time, lasts for an extended period (months, years, or a lifetime), and adversely affects the patient’s function or well-being.24 Chronic pain has been further subclassified into chronic malignant and chronic nonmalignant pain. Chronic pain may accompany a disease process such as cancer, human immunodeficiency virus (HIV) infection and acquired immune deficiency syndrome (AIDS), arthritis or degenerative joint disease, osteoporosis, chronic obstructive pulmonary disease, neurological disorders (e.g., multiple sclerosis, cerebrovascular disease), fibromyalgia, sickle cell disease, cystic fibrosis, and diabetes. It may also be associated with an injury that has not resolved within an expected period of time, such as low back pain, trauma, spinal cord injury, reflex sympathetic dystrophy, or phantom limb pain.

Additionally, the American Geriatric Society (AGS) Panel on Persistent Pain in Older Persons14 has classified persistent pain in pathophysiological terms that assist the health care professional to determine the cause of pain and select the appropriate pain management interventions. The four pain subcategories that have been delineated are nociceptive pain (visceral or somatic pain resulting from stimulation of pain receptors), neuropathic pain (pain caused by peripheral or central nervous system stimulation), mixed or unspecified pain (having mixed or unknown pain mechanisms), and pain due to psychological disorders.

### Barriers to Optimal Pain Assessment

Inadequate pain control is not the result of a lack of scientific information. Over the last two decades, a plethora of research has generated knowledge about pain and its management. Reports that document the inability or unwillingness of health care professionals to use knowledge from research and advances in technology continue to appear in the nursing and medical literature. The armamentarium of knowledge is available to assist professionals in the successful assessment and management of pain; the problems lie in its misuse or lack of use. Undertreatment of pain often results from clinicians’ failure or inability to evaluate or appreciate the severity of the patient’s problem. Although accurate and timely pain assessment is the cornerstone of optimal pain management, studies of nurses and other health care professionals continue to demonstrate the contribution of suboptimal assessment and documentation to the problem of inadequate pain management.2,24–27

Multiple barriers to the achievement of optimal pain assessment and management have been identified (Table 5–1).25,29–35 The knowledge and attitudes of health care professionals toward pain assessment are extremely important, because these factors influence the priority placed on pain treatment.36

Recognition of the widespread inadequacy of pain assessment and management has prompted corrective efforts within many health care disciplines, including nursing, medicine, pharmacy, and pain management organizations. Representatives

from various health care professional groups have convened to develop clinical practice guidelines and quality assurance standards for the assessment and management of acute, cancer, and end-of-life pain.\textsuperscript{5,6,18,19,37–42} The establishment of a formal monitoring program to evaluate the efficacy of pain assessment and interventions has been encouraged. The Agency for Health Care Policy and Research (AHCPR) Acute and Cancer Pain Practice Guidelines, The American Pain Society (APS) Quality Assurance Standards, The Oncology Nursing Society (ONS) Position Paper on Cancer Pain Management, the APS Position Statement on Treatment of Pain at the End of Life, the AGS Panel on Persistent Pain in Older Persons, the American Medical Directors Association (AMDA) Pain Guidelines, APS Guidelines for the Management of Cancer Pain in Adults and Children, and the National Comprehensive Cancer Network (NCCN) Guidelines are reflective of the national trend to assess quality of care in high-incidence patients by monitoring outcomes as well as assessing and managing pain. The AHCPR recommends the following “ABCDE” mnemonic list as a summary of the clinical approach to pain assessment and management:

\textit{A}—Ask about pain regularly. Assess pain systematically.
\textit{B}—Believe the patient and family in their reports of pain and what relieves it.
\textit{C}—Choose pain control options appropriate for the patient, family, and setting.
\textit{D}—Deliver interventions in a timely, logical, and coordinated fashion.
\textit{E}—Empower patients and their families. Enable them to control their course to the greatest extent possible.

Members of the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) routinely inquire about pain assessment and management practices and quality assurance activities designed to monitor patient satisfaction and outcomes within institutions. Revised JCAHO standards\textsuperscript{45} for assessing and managing pain in hospital, ambulatory, home care, and long-term care have been released. The JCAHO supports “institutionalizing pain management” and using an interdisciplinary approach to effect change in health care organizations. It also recommends that culturally sensitive pain rating scales appropriate to a patient’s age be available and that new or existing assessment forms include pain. Additionally, the APS has created the phrase “Pain: The Fifth Vital Sign” to heighten health care provider awareness of pain assessment and treatment.\textsuperscript{44} The continuous quality improvement (CQI) process is continuous, with the achievement of low levels of reported pain severity and of pain-related behaviors as an appropriate objective.\textsuperscript{45} Providing health care systems within a CQI perspective of patient-centered care requires that health care professionals seek opportunities to improve pain management by improving assessment processes to produce the desired outcome of decreased pain for patients.

Health care reform processes such as managed care require that patients be discharged sooner, without adequate time to assess pain or to evaluate newly prescribed pain management regimens. Therefore, the prevalence of inadequate pain assessment and management may be even greater than reported, because more persons may be suffering silently in their homes. An adequate pain assessment may not have been done or documented. Health care professionals may not believe patients’ reports of pain and may not take time to communicate, care, or understand the meaning of the pain experience for the patient. With the influences and increasing demands of managed care and changes in the delivery of health care, pain assessment and management may not be a priority.

\textbf{Process of Pain Assessment}

Accurate pain assessment is the basis of pain treatment; it is a continuous process that encompasses multidimensional factors. In formulating a pain management plan of care, an assessment is crucial to identify the pain syndrome or the cause of pain. A comprehensive assessment addresses each type of pain and includes the following: a detailed history, including an assessment of the pain intensity and its characteristics (Figure 5–1); a physical examination with pertinent neurological examination, particularly if neuropathic pain is suspected; a psychosocial and cultural assessment; and an appropriate diagnostic workup to determine the cause of pain.\textsuperscript{5,40} Attention should be paid to any discrepancies between patients’ verbal descriptions of pain and their behavior and appearance. The physical examination should focus on an examination of the painful areas as well as common referred pain locations. In frail or terminally ill patients, physical examination maneuvers and diagnostic tests should be performed only if the findings will potentially change or facilitate the treatment plan. The burden and potential discomfort of any diagnostic test must be weighed against the potential benefit of the information obtained.\textsuperscript{46} Ongoing and subsequent evaluations are necessary to determine the effectiveness of pain relief measures and to identify any new pain.

Patients or residents should be asked whether they have pain (screened for pain) on admission to a hospital, clinic, nursing home, hospice, or home care agency. If pain or discomfort is reported, a comprehensive pain assessment should be performed at regular intervals, whenever there is a change in the pain, after analgesic administration, and after any modifications in the pain management plan. The frequency of a pain assessment is determined by the patient’s or resident’s clinical situation. Pain assessment should be individualized and documented so that all multidisciplinary team members involved will have an understanding of the pain problem. Information about the patient’s pain can be obtained from multiple sources: observations, interviews with the patient and significant others, reviews of medical data, and feedback from other health care providers.

Although pain is uniquely personal and subjective, its management necessitates certain objective standards of care and
The first opportunity to understand the subjective experience is at the perceptual level. Perception incorporates the patient’s self-report and the results of pain assessment accomplished by the health care provider. Perception is “the act of perceiving, to become aware directly in one’s mind, through any of the senses; especially to see or hear, involving the process of achieving understanding or seeing all the way through”; assessment is defined as “the act of assessing, evaluating, appraising, or estimating by sitting beside another.”

Perception is an abstract process in which the person doing the perceiving is not just a bystander but is immersed in understanding of the other’s situation. Perception is influenced by “higher-order” processes that characterize the cognitive and emotional appraisal of pain—what people feel and think about their pain and their future with the pain. Perception also includes the interpersonal framework in which the pain is experienced (with family or friends or alone), the meaning or reason for the pain, the person’s coping pattern or locus of control, the presence of additional symptoms, and others’ concerns (e.g., family members’ depression or anxiety). Alternatively, assessment is a value judgment that occurs by observing the other’s experience.

Assessment and perception of the pain experience of a patient at the end of life is essential before planning interventions. However, the quality and usefulness of any assessment is only as good as the ability of the assessor to be thoroughly focused on the patient. This means listening empathetically, maintaining open communication, and validating overall care. Sources: © 1996 Regina Fink, University of Colorado Health Science Center, used with permission; and Wong D, Whaley L. Clinical Handbook of Pediatric Nursing, 2nd ed. St. Louis: CV Mosby, 1986, p. 373.

Figure 5–1. A pocket pain assessment guide (front and back) for use at the bedside. The health care professional can use this guide to help the patient identify the level and intensity of pain and to determine the best approach to pain management in the context of practice. The first opportunity to understand the subjective experience is at the perceptual level. Perception incorporates the patient’s self-report and the results of pain assessment accomplished by the health care provider. Perception is “the act of perceiving, to become aware directly in one’s mind, through any of the senses; especially to see or hear, involving the process of achieving understanding or seeing all the way through”; assessment is defined as “the act of assessing, evaluating, appraising, or estimating by sitting beside another.”

Perception is an abstract process in which the person doing the perceiving is not just a bystander but is immersed in understanding of the other’s situation. Pain Assessment

Pain does not occur in isolation. Other symptoms and concerns experienced by the patient compound the suffering associated with pain. Total pain has been described as the sum of all of the following interactions: physical, emotional/psychological, social, spiritual, bureaucratic, and financial (Figure 5-2). At times, patients describe their whole life as painful. The provision of palliative care to relieve pain and suffering is based on the conceptual model of the whole person experiencing “total pain.”

It is not always necessary or relevant to assess all dimensions of pain in all patients or in every setting. At the very least, both the sensation of pain and the response to pain must be considered during an assessment. The extent of the assessment should be dictated by its purpose, the patient’s condition or stage of illness, the clinical setting, feasibility, and the relevance of a particular dimension to the patient or health care provider. For example, a comprehensive assessment may be appropriate for a patient in the early stage of palliative care, whereas only a pain intensity score is needed when evaluating a patient’s response to an increased dose of analgesic. Incorporation of the multidimensional factors described in the following paragraphs into the pain assessment will ensure a comprehensive approach to understanding the patient’s pain experience.

Multifactorial Model for Pain Assessment

Pain is a complex phenomenon involving many interrelated factors. The multifactorial pain assessment model is based on the work of a number of researchers over the last three decades. Melzack and Casey suggested that pain is determined by the interaction of three components: the sensory/discriminative (selection and modulation of pain sensations), the motivational/affective (affective reactions to pain via the brain’s reticular formation and limbic system), and the cognitive (past or present experiences of pain). Evidence presented by Ahles and coworkers supported the usefulness of a multidimensional model for cancer-related pain by describing the following theoretical components of the pain experience: physiologic, sensory, affective, cognitive, and behavioral. McGuire expanded the work of Ahles and colleagues by proposing the integration of a sociocultural dimension to the pain model. This sociocultural dimension, comprising a broad range of ethnocultural, demographic, spiritual, and social factors, influences an individual’s perception of and responses to pain. Bates proposed a biocultural model, combining social learning theory and the gate control theory, as a useful framework for studying and understanding cultural influences on human pain perception, assessment, and response. She believed that different social communities (ethnic groups) have different cultural experiences,
Symptom Assessment and Management

attitudes, and meanings for pain that may influence pain perception, assessment, tolerance, and neurophysiological, psychological, and behavioral responses to pain sensation. Hester proposed an environmental component, referring to the setting, environmental conditions, or stimuli that affect pain assessment and management. Excessive noise, lighting, or adverse temperatures may be sources of stress for individuals in pain and may negatively affect the pain experience.

Given the complexity of the interactions among the factors, if a positive impact on the quality of life of patients is the goal of palliative care, then the multifactorial perspective provides the foundation for assessing and ultimately managing pain. Some questions that can guide the nurse’s multifactorial pain assessment are reviewed in Table 5–2.

### Physiological and Sensory Factors

The physiological and sensory factors of the pain experience explain the cause and characterize the person’s pain. Patients should be asked to describe their pain, including its quality, intensity, location, temporal pattern, and aggravating and alleviating factors. The five key factors included in the pain assessment are outlined in Figure 5–1. In the palliative care setting, the patient’s cause of pain may have already been determined. However, changes in pain location or character should not always be attributed to these preexisting causes but should instigate a reassessment. Treatable causes, such as infections or fractures, may be the cause of new or persistent pain.

**Words.** Patients are asked to describe their pain using words or qualifiers. Neuropathic or deafferentation pain may be described as burning, shooting, numb, radiating, or lancinating pain; visceral pain is poorly localized and may be described as squeezing, cramping, or pressure; somatic pain is described as achy, throbbing, and well-localized. Additionally, some patients may not actually complain of pain but may say they feel discomfort. Identifying the qualifiers enhances understanding of the pain’s cause and should optimize pain treatment. Not doing so may result in an incomplete pain profile. Table 5–3 summarizes various pain types, qualifiers, etiological factors, and choice of analgesia based on pain type.

**Intensity.** Although an assessment of intensity captures only one aspect of the pain experience, it is the most frequently used parameter in clinical practice. Asking for the patient’s or resident’s pain intensity or pain score will objectively measure how much pain a person is experiencing. Pain intensity should be evaluated not only at the present level, but also at its least or best, worst, and with movement. Patients should also be asked how their pain compares with yesterday or with their worst day. A review of the amount of pain after the administration of analgesics, adjuvant drugs, and/or nonpharmacological approaches can also add information about the patient’s level of pain. Pain intensity can be measured quantitatively with the use of a visual analog scale, numeric rating scale, verbal descriptor scale, faces scale, or pain thermometer. In using these tools, patients typically are asked to rate their pain on a scale of 0 to 10: no pain = 0; mild pain is indicated by a score of 1 to 3; moderate pain, 4 to 6; and severe pain, 7 to 10. No single scale is appropriate for all patients. During instrument selection, the nurse must consider the practicality, ease, and acceptability of the instrument’s use by terminally ill patients (for a description of these instruments, refer to Table 5–5). To ensure consistency, staff should carefully document which scale worked best for the patient, so that all members of the health care team will be aware of the appropriate scale to use.

Location. More than 75% of persons with cancer have pain in two or more sites; therefore, it is crucial to ask questions about the location of a patient's pain. Using an assessment sheet with a figure demonstrating anterior and posterior views or encouraging the patient to point or place a finger on the area involved will provide more specific data than verbal self-report does. Separate pain histories should be acquired for each major pain complaint, since their causes may differ and the treatment plan may need to be tailored to the particular type of pain. For example, neuropathic pain may radiate and follow a dermatomal path; pain that is deep in the abdomen may be visceral; and when a patient points to an area that is well-localized and nonradiating, the pain may be somatic indicating bone metastasis. Metastatic bone pain is the most common pain syndrome in cancer patients, with up to 79% of patients experiencing severe pain before palliative therapy. For further information, visit the website, http://www.whocancerpain.wisc.edu.

Duration. Learning whether the pain is persistent, intermittent, or both will guide the nurse in the selection of interventions. Patients may experience "breakthrough" pain—an intermittent, transitory flare of pain. This type of pain requires a fast-acting opioid, whereas persistent pain is usually treated with long-acting, continuous-release opioids. Patients with progressive diseases such as cancer and AIDS may experience chronic pain that has an ill-defined onset and unknown duration.

Aggravating and Alleviating Factors. If the patient is not receiving satisfactory pain relief, inquiring about what makes the pain better or worse—the alleviating and aggravating factors—will assist the nurse and other health care professionals in determining which diagnostic tests need to be ordered or which nonpharmacological approaches can be incorporated into the plan of care. This is also an important aspect of the initial pain assessment, because it helps to determine the cause of the pain. Pain interference with functional status can be measured by determining the pain's effects on activities such as walking, sleeping, eating, energy, activity, relationships, sexuality, and mood. Researchers have found that pain interference with functional status is highly correlated with pain intensity scores; for example, a pain intensity score greater than 4 has been shown to significantly interfere with daily functioning.

Affective Factor

The affective factor includes the emotional responses associated with the pain experience and, possibly, such reactions as depression, anger, distress, anxiety, decreased ability to concentrate, mood disturbance, and loss of control. A person's feelings of distress, loss of control, or lack of involvement in the plan of care may affect outcomes of pain intensity and patient satisfaction with pain management.
Cognitive Factor

The cognitive factor of pain refers to the way pain influences the person's thought processes; the way the person views himself or herself in relation to the pain; the knowledge, attitudes, and beliefs the person has about the pain; and the meaning of the pain to the individual. Past experiences with pain may influence one's beliefs about pain. Whether the patient feels that another person believes in his or her pain also contributes to the cognitive dimension. Bostrom and colleagues\textsuperscript{60} interviewed 30 palliative care patients with cancer-related pain to examine their perceptions of the management of their pain. Patients expressed a need for open communication with health care professionals about their pain problem and a need for being involved in the planning of their pain treatment. Those who felt a trust in their health care organization, their nurse, and their doctor described an improved ability to participate in their pain management plan.

Patients’ knowledge and beliefs about pain play an obvious role in pain assessment, perception, function, and response to treatment. Patients may be reluctant to tell the nurse when they have pain; they may attempt to minimize its severity, may not know they can expect pain relief, and may be concerned about taking pain medications for fear of deleterious effects. A comprehensive approach to pain assessment includes evaluation of the patient’s knowledge and beliefs about pain (Table 5–4) and its management and common misconceptions about analgesia.\textsuperscript{29,35,61,62}

Behavioral Factor

Pain behaviors may be a means of expressing pain or a coping response.\textsuperscript{63,64} The behavioral factor describes actions the person exhibits related to the pain, such as verbal complaints, moaning, groaning, crying, facial expressions, posturing, splinting, lying down, pacing, rocking, or suppression of the expression of pain. Other cues can include anxious behaviors, insomnia, boredom, inability to concentrate, restlessness, and fatigue.\textsuperscript{65} Unfortunately, some of these behaviors or cues may relate to causes or symptoms other than pain. For example, insomnia caused by depression may complicate the pain assessment.

Nonverbal expression of pain can complement, contradict, or replace the verbal complaint of pain\textsuperscript{66} (see later discussion). Observing a patient’s behavior or nonverbal cues, understanding the meaning of the pain experience to the patient, and collaborating with family members and other health care professionals to determine their thoughts about the patient’s pain are all part of the process of pain assessment.

The behavioral dimension also encompasses the unconscious or deliberate actions taken by the person to decrease the pain. Pain behaviors include, but are not limited to, using both prescribed and over-the-counter analgesics; seeking medical assistance; using nonpharmacological approaches; and other coping strategies such as removing aggravating factors (e.g., noise and light). Behaviors used to control pain in patients with advanced-stage disease include assuming special positions, immobilizing or guarding a body part, rubbing, and adjusting pressure to a body part.

Sociocultural Factor

The sociocultural factor encompasses all of the demographic variables of the patient experiencing pain. The impacts of these factors (e.g., age, gender, ethnicity, spirituality, marital status, social support) on pain assessment, treatment, and outcomes have been examined in the literature. Although many studies have promoted each individual dimension, few have concentrated on their highly interactive nature. Ultimately, all of these factors can influence pain assessment.

</table>

Age. Much of the pain literature has called attention to the problem of inadequate pain assessment and management in the elderly in a palliative care setting. Elderly patients suffer disproportionately from chronic painful conditions and have multiple diagnoses with complex problems and accompanying pain. Elders have physical, social, and psychological needs distinct from those of younger and middle-aged adults, and they present particular challenges for pain assessment and management. Pain assessment may be more problematic in elderly patients because their reporting of pain may differ from that of younger patients due to their increased stoicism.35 Elderly people often present with failures in memory, depression, and sensory impairments that may hinder history taking; they may also underreport pain because they expect pain to occur as a part of the aging process.67,68 Moreover, dependent elderly people may not report pain because they do not want to bother the nurse or doctor and are concerned that they will cause more distress in their family caregivers.89

Studies have documented the problem of inadequate pain assessment in the elderly.70 Cleeland and colleagues2 studied 1308 outpatients with metastatic cancer and found that those 70 years of age or older were more likely to have inadequate pain assessment and analgesia. Approximately 40% of elderly nursing home patients with cancer experience pain every day, according to Bernabei and colleagues,71 who reviewed Medicare records of more than 13,625 cancer patients aged 65 years or older who were discharged from hospitals to almost 1500 nursing homes in five states. Pain assessment was based on patient self-report and determined by a multidisciplinary team of nursing home personnel involved with the patients. Of the more than 4000 patients who complained of daily pain, 16% were given a nonopioid drug, 32% were given codeine or another weak opioid, 26% received morphine, and 26% received no analgesic medication at all. As age increased, a greater proportion of patients in pain received no analgesic drugs (21% of patients aged 65 to 74 years, 26% of those aged 75 to 84 years, and 30% of those 85 years of age and older; \( P = 0.001 \)). Therefore, it is imperative to pay particular attention to pain assessment in the elderly patient, so that the chance of inadequate analgesia is decreased. Dementia, cognitive and sensory impairments, and disabilities can make pain assessment and management more difficult. Also, residents in long-term care facilities are likely to have multiple medical problems that can cause pain.

**Gender.** Gender differences affect sensitivity to pain, pain tolerance, pain distress, willingness to report pain, exaggeration of pain, and nonverbal expression of pain.25–27 Multiple studies have demonstrated that men show more stoicism than women do, women exhibit lower pain thresholds and less tolerance to noxious stimuli than men, women become more upset when pain prevents them from doing things they enjoy, and women seek care of the pain sooner and respond better to \( \kappa \)-opioid analgesics than do men.74–79 The mechanism of pain was studied in 181 men and women with advanced cancer.80 Women experienced more visceral pain, whereas men had more somatic pain (bone metastases). Neuropathic pain was observed in both women and men yet was more severe than the other pain types. Whether women are more willing to report pain than men or experience pain differently from men is unclear. However, beliefs about gender differences may affect nurses’ interpretation and treatment of patients’ pain. Nurses and other health care professionals need to be mindful of possible gender differences when assessing pain and planning individualized care for persons in pain.

**Ethnicity.** Despite controversies and uncertainties, the relationship between ethnicity and pain is an important area for study. The term *ethnicity* refers to one or more of the following3: (1) a common language or tradition, (2) shared origins or social background, and (3) shared culture and traditions that are distinctive, passed through generations, and create a sense of identity. Ethnicity may be a predictor of pain expression and response. While assessing pain, it is important to remember that certain ethnic groups and cultures have strong beliefs about expressing pain and may hesitate to complain of unrelied pain.82 The biocultural model of Bates and associates83 proposed that culturally accepted patterns of ethnic meanings of pain may influence the neurophysiological processing of nociceptive information that is responsible for pain threshold, pain tolerance, pain behavior, and expression. Thus, the manner in which a person reacts to the pain experience may be strongly related to cultural background. The biocultural model also hypothesizes that social learning from family and group membership can influence psychological and physiological processes, which in turn can affect the perception and modulation of pain. Bates and colleagues83 stressed that all individuals, regardless of ethnicity, have basically similar neurophysiological systems of pain perception. Early clinical studies of pain expression and culture concluded that the preferred values and traditions of culture affected an individual’s handling and communication of pain.44–46

Other studies have reported that members of minority groups are at risk for undertreatment of pain.57,68 However, caution must be used when interpreting the results of these studies, because the findings may be due to variations in the pain experience, pain behavior, the language of pain, or staff perception and subsequent pain management.87 When caring for any patient who is experiencing pain, it is important for the nurse to avoid cultural stereotyping and to provide culturally sensitive assessment and educational materials, enlisting the support of an interpreter when appropriate.

**Marital Status and Social Support.** The degree of family or social support in a patient’s life should be assessed, because these factors may influence the expression, meaning, and perception of pain and the ability to comply with therapeutic recommendations. Few studies have examined the influence of marital status on pain experience and expression. Dar and coworkers88 studied 40 patients (43% women, 55% men) with metastatic cancer pain and found that patients minimized their pain when their spouses were present. When asked if and
how their pain changed in the presence of spouses, 40% of the patients said the pain was better and 60% reported no change; none reported that the pain was worse. The majority (64%) of patients agreed that they conceal their pain so that their spouses will not be upset, even though spouses were generally accurate in their estimates of the patients’ pain levels. Almost all patients reported a very high degree of satisfaction with the way their spouses helped them cope with pain.

**Spirituality.** Spross and Wolff Burke91 believed that the spiritual dimension mediates the person’s holistic response to pain and pain expression and influences how the other aspects of pain are experienced. Whereas pain refers to a physical sensation, suffering refers to the quest for meaning, purpose, and fulfillment. Although pain is often a source of suffering, suffering may occur in the absence of pain. Many patients believe that pain and suffering are meaningful signs of the presence of a higher being and must be endured; others are outraged by the pain and suffering they must endure and demand alleviation. The nurse must verify the patients’ beliefs and give them permission to verbalize their personal points of view. Assessing a patient’s existential view of pain and suffering is important because it can affect the processes of healing and dying. Understanding patients’ use of spiritual comfort strategies is also an area to explore. Dunn and Horgas92 found that elderly women and older patients of minority background reported using religious coping strategies (prayer or spiritual comfort) to manage their pain more often than did older Caucasian men. Spiritual assessment is covered in greater detail in Chapter 30.

**Environmental Factor**

The environmental factor refers to the context of care, the setting, or the environment in which the person receives pain management. Creating a peaceful environment free from bright lights, extreme noise, and excessive heat or cold may assist in alleviating the patient’s pain.

Additionally, particular nurse or physician specialists may perceive an individual’s pain differently. A review of the literature suggests that nurses and other health care professionals are inconsistent in their reliance on patient self-report as a major component in the assessment process. Agreement between patients’ perceptions and health care professionals’ perceptions was relatively low and was generally an inadequate substitute for patients’ reports of pain.93,94 Ferrell and colleagues95 found that 91% of nurses surveyed reported asking patients about the intensity of their pain, yet only 45% believed that a patient’s report of pain was the most important factor in determining pain intensity. It is not apparent whether this belief resulted from a deficiency of information, lack of time to perform an assessment, or interference of values or bias in the decision-making process. Health care providers’ ratings corresponded more with patients’ ratings when pain was severe.94,96 Additionally, when nurses’ pain assessment was documented over time, early assessments were more accurate than later ones.97 Werner and colleagues98 suggested that patients who are cognitively intact might have better pain assessments.

A multifactorial framework describing the influences of all of these factors on the assessment of pain and the pain experience is desirable to attain positive pain outcomes. The factors comprising the framework are assumed to be interactive and interrelated. Use of this framework for pain assessment has clear implications for clinical practice and research.

**Quantitative Assessment of Pain**

Although pain is a subjective, self-reported experience of the patient, the ability to quantify the intensity of pain is essential to monitoring a patient’s responsiveness to analgesia.

**Pain Intensity Assessment Scales**

The most commonly used pain intensity scales—the visual analog scale (VAS), the numeric rating scale (NRS), the verbal descriptor scale (VDS), the Wong-Baker FACES pain scale, the Faces Pain Scale (FPS), Faces Pain Scale-Revised (FPS-R), and the pain thermometer—are illustrated in Figure 5–3 and reviewed in Table 5–5 with advantages and disadvantages delineated. These scales have proved to be very effective, reproducible means of measuring pain and other symptoms, and they can be universally implemented and regularly applied in many care settings. How useful these tools are in the assessment of pain in the palliative care patient is a question that still needs to be answered.

Although no one scale is appropriate or suitable for all patients, Dalton and McNaul123 recommended universal adoption of a 0-to-10 scale, rather than a 0-to-5 or a 0-to-100 scale, for clinical assessment of pain intensity in adult patients. Jensen and colleagues124 examined the maximum number of levels needed to measure pain intensity in patients with chronic pain and concluded that an 11-point scale (0 to 10) provided sufficient levels of discrimination when compared with a 0-to-100 scale. Standardization may promote collaboration and consistency in evaluation among caregivers in multiple settings (i.e., inpatient, outpatient, and home care or hospice environments). It would facilitate multiple studies of pain across sites. Collection of comparative data would be enabled, allowing for simplification of the analytical process when conducting research. Detailed explanation of how to use the pain scales is necessary before use by patients in any clinical care area.

Another area deserving attention is health care professionals’ inconsistent use of word anchors on pain intensity scales. The intention behind the use of a word anchor to discriminate pain intensity is to provide a common endpoint; although that point may have not been reached by a patient, it would provide a place for any pain experienced to date or pain that may be experienced in the future. Some of the common endpoint word anchors that have been used are “worst possible
Pain Assessment

107

pain, “pain as bad as it can be,” “worst pain imaginable,” “worst pain you have ever had,” “most severe pain imaginable,” and “most intense pain imaginable.” Inconsistent or different word anchors may yield different pain reports. Therefore, it is important to come to some consensus about consistent use of word anchors.

### Comparison of Pain Scales

Several studies have been systematically reviewed, and although many are limited in sample size and population, a positive correlation was demonstrated among the VAS, VDS, NRS, Wong-Baker FACES scale, and Bieri FPS. Each of the commonly

### Pain Intensity Assessment Scales

<table>
<thead>
<tr>
<th>Scale</th>
<th>Description</th>
<th>Advantages</th>
<th>Disadvantages</th>
</tr>
</thead>
</table>
| A. Visual Analog Scale (VAS) | A vertical or horizontal line of 10 cm (or 100 mm) in length anchored at each end by verbal descriptors (e.g., no pain and worst possible pain). Patients are asked to make a slash mark of X on the line at the place that represents the amount of pain experienced. | Positive correlation with other self-reported measures of pain intensity and observed pain behaviors.\(^{90,100}\)
Sensitive to treatment effects and distinct from subjective components of pain.\(^{101,102}\)
Qualities of ratio data with high number of response categories make it more sensitive to changes in pain intensity.\(^{100,103}\) Parametric statistics can be used to analyze data. | Scoring may be more time-consuming and involve more steps.\(^{99}\) Patients may have difficulty understanding and using a VAS measure.\(^{104}\) Too abstract for many adults, and may be difficult to use with geriatric patients/residents, non–English-speaking patients, and patients with physical disability, immobility, or reduced visual acuity, which may limit their ability to place a mark on the line.\(^{104–106}\) |
| B. Numeric Rating Scale | The number that the patient gives represents his/her pain intensity from 0 to 10 with the understanding that 0 = no pain and 10 = worst possible pain. | Validity and demonstrated sensitivity to treatments that affect pain intensity.\(^{107}\)
Verbal administration to patients allows those by phone or who are physically and visually disabled to quantify pain intensity.\(^{108}\) Ease in scoring, high compliance, high number of response categories.\(^{99,108}\) Scores may be treated as interval data and are correlated with VAS.\(^{109}\) | Lack of research comparing sensitivity with that of VAS. |
| C. Verbal Descriptor Scale (VDS) | Adjectives reflecting extremes of pain are ranked in order of severity. Each adjective is given a number which constitutes the patient’s pain intensity. | Short, easily administered to patients, easily comprehended, high compliance.\(^{99}\) Easy to score and analyze data on an ordinal level.\(^{104}\) Validity is established.\(^{101}\) Sensitivity to treatments that are known to affect pain intensity.\(^{103}\) | Less reliable among illiterate patients and persons with limited English vocabulary.\(^{109}\) Patients must choose one word to describe their pain intensity even if no word accurately describes it.\(^{99}\) Variability in use of verbal descriptors is associated with affective distress.\(^{104}\) Scores on VDS are considered ordinal data; however, the distances between its descriptors are not equal but categorical. Thus, parametric statistical procedures may be suspect.\(^{108}\) |
| D. FACES Scale (Wong-Baker\(^{111}\)) | The scale consists of six cartoon-type faces. The “no pain” (0) face shows a widely smiling face and the “most pain” (5) face shows a face | Validity is supported by research reporting that persons from many cultures recognize facial expressions and identify them in similar | Presence of tears on the “most pain” face may introduce cultural bias if the scale is used by adults from cultures not sanctioning crying in |
used rating scales appear to be adequately valid and reliable as a measure of pain intensity in both cancer patients and elders.

The VAS has been evaluated comprehensively by many researchers over the years and has usually been found to be valid and reliable. However, some patients find it difficult to convert a subjective sensation into a straight line. Herr and Mobily studied 49 senior citizens 65 years of age with reported leg pain to determine the relationships among various pain intensity measures, to examine the ability of patients to use the tools correctly, and to determine elderly people’s preferences. The VAS consisted of 10-cm horizontal and vertical lines; the VDS had six numerically ranked choices of word descriptors, including “no pain,” “mild pain,” “discomforting,” “distressing,” “horrible,” and “excruciating”; the NRS had numbers from 1 to 20; and the pain thermometer had seven choices, ranging from “no pain” to “pain as bad as it could be.” The scale preferred by most respondents was the VDS. Of the two VAS scales, the vertical scale was chosen most often because the elderly subjects had a tendency to conceptualize the vertical presentation more accurately. Elderly patients may have deficits in abstract ability that make the VAS difficult to use. Other researchers have noted that increased age is associated with an increased incidence of incorrect response to the VAS.

Paice and Cohen used a convenience sample of 50 hospitalized adult cancer patients with pain to study their preference in using the VAS, the VDS, and the NRS. Fifty percent of the patients preferred using the NRS. Fewer patients preferred the VDS (38%), and the VAS was chosen infrequently (12%). Twenty percent of the patients were unable to complete the VAS or had difficulty in doing so. Problems included needing assistance with holding a pencil, making slash marks that were too wide or not on the line, marking the wrong end of the line, and asking to have instructions read repeatedly during the survey.

Additional problems exist with use of the VAS. When multiple horizontal scales are used to measure different aspects or dimensions (e.g., pain intensity, distress, depression), subjects...
tend to mark all of the scales down the middle. Pain intensity has been noted to be consistently higher on each scale for depressed and anxious patients compared with nondepressed, nonanxious patients. Photocopying of VAS forms may result in distortion so that the scales may not be exactly 10 cm long and the reliability of measurement may be in question. Physical disability or decreased visual acuity may limit the ability of the palliative care patient to mark the appropriate spot on the line. The VAS also requires pencil and paper and requires the patient to be knowledgeable about various English pain adjectives. In conclusion, a VAS to rate their pain. Of those able to choose, the VAS was the most commonly selected (52%); 29% chose the NRS; 19% preferred the FPS. More men than women and those residents with moderate to severe pain preferred the NRS; a higher percentage of minority (Hispanic) residents preferred the FPS.

Findings from various studies indicated that patients used the FPS to measure pain appropriately and that the FPS should be considered an alternative to the NRS or VAS in various populations. However, the literature regarding choice of scale among ethnic groups is equivocal. Carey and colleagues asked hospitalized patients which of several scales they preferred to use: a modified Wong-Baker FACES scale (tears were removed), an NRS, or a vertical VAS. They found that less educated adults, both African American and Caucasian American, preferred the Wong-Baker FACES scale; more educated patients preferred the NRS. Stuppy also found that patients preferred the FPS to the NRS, VAS, or VDS, with no significant differences noted between African American and Caucasian American participants. Taylor and Herr discovered that both cognitively impaired and intact African American elders preferred the FPS to the NRS or the VDS, and they found support for the ordinal nature of the FPS. Participants clearly agreed that the FPS represented pain but also agreed that the FPS may represent other constructs, such as sadness or anger, depending how they were cued; this suggests that the FPS may be measuring pain affect, not just intensity. Jensen and coworkers examined six pain rating scales, including the seven-point FPS, in persons with cerebral palsy and also found that the FPS measured more than just pain intensity; it may be reflective of a distress dimension associated with pain and its impact on functioning.

In summary, a variety of scales have been used to assess pain in many different patient populations. Each has been widely used in clinical research and practice. Little research has been done on the appropriateness of pain scales in the palliative care setting. Intellectual understanding and language skills are prerequisites for such pain assessment scales as the VAS and VDS. These scales may be too abstract or too difficult for patients in the palliative care setting. Because most dying patients are elderly, simple pain scales, such as the NRS or a faces scale, may be more advantageous.

**Multifactorial Pain Instruments**

There are several pain measurement instruments that can be used to standardize pain assessment, incorporating patient demographic factors, pain severity scales, pain descriptors, and other questions related to pain. Four instruments have been considered short enough for routine clinical use with cancer patients. All of these instruments provide a quick way of measuring pain subjectively; however, their use in seriously ill, actively dying patients needs further study (see the AHCPR Acute and Cancer Pain Guidelines for a more comprehensive description of many of these instruments).

**Short Form McGill Pain Questionnaire.** A short form of the McGill Pain Questionnaire (SF-MPQ) has been developed and includes 15 words to describe pain. Each word or phrase is rated on a four-point intensity scale (0 = none, 1 = mild, 2 = moderate, and 3 = severe). Three pain scores are derived from the sum of the intensity rank values of the words chosen for sensory, affective, and total descriptors. Two pain measures are also included in the SF-MPQ: the Present Pain Intensity Index (PPI) and a 10-cm VAS. The SF-MPQ has demonstrated reliability and validity and is available in multiple languages.

**Brief Pain Inventory.** The Brief Pain Inventory (BPI) is a multifactorial instrument that address pain etiology, history, intensity, quality, location, and interference with activities. Patients are asked to rate the severity of their pain at its worst, least, and average and at present. Using an NRS (0 to 10), patients are also asked for ratings of how much their pain interferes with walking ability, mood, general activity, work, enjoyment of life, sleep, and relationships with others. The BPI also asks patients to represent the location of their pain on a drawing and asks about the cause of pain and the duration of pain relief.

**Memorial Pain Assessment Card.** The Memorial Pain Assessment Card (MPAC) is a simple valid tool consisting of three VAS, for pain intensity, pain relief, and mood, and one VDS to describe the pain. The MPAC can be completed by patients in 20 seconds or less and can distinguish between pain intensity, relief, and psychological distress.

**City of Hope Patient and Family Pain Questionnaires.** The City of Hope Patient and Family Pain Questionnaires were designed to measure the knowledge and experience of patients with chronic cancer pain and their family caregivers. The 16-item surveys use an ordinal scale format and can be administered in inpatient or outpatient settings.

Because terminally ill patients have multiple symptoms, it is impossible to limit an assessment to only the report of pain. Complications or symptoms related to the disease process may
exacerbate pain, or interventions to alleviate pain may cause side effects that result in new symptoms or a worsening of other symptoms, such as constipation or nausea. Symptoms such as fatigue and anxiety are distressful and may affect quality of life in seriously ill cancer and noncancer patients. Therefore, pain assessment must be accompanied by assessment of other symptoms. Various surveys or questionnaires not only assess pain but also incorporate other symptoms into the assessment process. Many of these instruments are discussed in other chapters.

Pain Assessment in Nonverbal or Cognitively Impaired Patients

The gold standard or primary source of pain assessment is the patient’s self-report. However, pain instruments that rely on verbal self-report and are very useful in the early stages of palliative care may not be practical for dying patients who cannot verbalize pain or for patients with advanced disease if delirium or cognitive failure is prevalent. The IASP notes that “pain is always subjective,” that “each individual learns about pain through experiences related to injury in early life,” and that “the inability to communicate verbally does not negate the possibility that an individual is experiencing pain and is in need of appropriate pain-relieving treatment.”

The potential for unrelied and unrecognized pain is greater in patients who cannot verbally express their discomfort. Older, nonverbal, and cognitively impaired patients are at increased risk for pain, as well as underassessment and undertreatment of pain. Patients who are nonverbal or have dementing conditions such as Alzheimer’s disease are usually excluded from pain studies, and pain assessment and treatment in this group are poorly understood.

The inability to communicate effectively due to impaired cognition and sensory losses is a serious problem for many patients with terminal illnesses. Cognitive failure develops in the majority of cancer patients before death, and agitated delirium is frequently observed in patients with advanced cancer. Loss of consciousness occurs in almost half of dying patients during the final three days of life. These complications have been shown in part to be significantly correlated with a higher dose requirement of opioids and the presence of icterus. Clearly, pain assessment techniques and tools are needed that apply to patients, whether mentally incompetent or nonverbal, who communicate only through their unique behavioral responses. Interpretation of the meaning of specific biobehavioral response patterns during episodes of pain could potentially reduce barriers to optimal pain assessment and management in nonverbal patients. An instrument that could detect a reduction in pain behaviors could assess the effectiveness of a pain management plan. However, because pain is not just a set of pain behaviors, the absence of certain behaviors would not necessarily mean that the patient was pain free.

It is important for nurses and other health care professionals to remember that pain is communicated through both verbal and nonverbal behaviors. Verbal self-reports, whenever possible, are still important to reflect the individual’s perception of pain. Because nonverbal pain behaviors may or may not concur with verbal reports, caution is necessary when assessing pain based solely on any single parameter. In addition to the appropriate use and selection of pain assessment instruments, the following points recommended by Taylor and Herr should be remembered when assessing pain in cognitively impaired older individuals: allow enough time for patients to understand questions and formulate answers; avoid overstimulation; ensure adequate lighting and hearing aids (if needed); and provide large print for ease of reading.

Pain Behaviors

It may be more complicated to assess nonverbal cues in the palliative care setting because terminally ill patients with chronic pain, in contrast to patients with acute pain, may not demonstrate any specific behaviors indicative of pain. It is also not satisfactory and even erroneous to assess pain by reliance on involuntary physiological bodily reactions, such as increases in blood pressure, pulse, or respiratory depth. Elevated vital signs may occur with sudden, severe pain; but they usually do not occur with persistent pain after the body reaches physiological equilibrium. However, the absence of behavioral or involuntary cues does not negate the presence of pain. Assessment of behavior for signs of pain during rest and movement provides a potentially valid and reliable alternative to verbal and physiological indices of pain. Examples of pain behaviors in cognitively impaired or nonverbal patients or residents are displayed in Table 5–6.

Pain indicators in elderly patients with dementia identified by nursing home staff members included specific physical repetitive movements, vocal repetitions, physical signs of pain, and changes in behavior from the norm for that person. Four distinct facial actions that have been consistently identified in pain expression are brow lowering, eye narrowing or closure, and raising the upper lip. Although facial expressions are related to pain intensity ratings on sensory and affective scales, facial assessment tools such as the Facial Action Coding System (FACS) are too time-consuming and laborious for use in the clinical setting. Furthermore, observations of facial expressions may not be valid in those patients with conditions that result in distorted facial expressions, such as Parkinson’s disease or stroke. Cultural influences on behavioral expressions and interpretation of behavior must also be considered.

The Pain Experience in Patients with Cognitive Failure

The experience or behavior of pain in individuals with cognitive failure or dementia may be altered or different from that of patients or residents who are cognitively intact. There is a tendency for patients with increased levels of cognitive impairment to report less severe pain. Lapolio and Sakla suggested some impairment of affective pain perception in patients...
Symptom Assessment and Management

with Lewy body dementia, because the Lewy bodies have been shown to occupy the hypothalamus and frontal cortex. Significantly increased pain tolerance in patients with mild dementia, reported by several experimental studies, implies that motivational-affective and cognitive-evaluative, not sensory-discriminative pain systems are affected: “In other words, mildly demented individuals seem to experience the same nociceptive sensations as nondemented individuals, but they fail to interpret these sensations as painful” (p. 103). If the patient’s anxiety and expectation of pain are decreased, impaired memory may reduce pain. The individual with memory impairments may also be unable to adapt to pain due to a loss of habituation to painful stimuli. Studies suggesting that pain reports in cognitively impaired individuals are decreased in intensity and frequency are probably related to a decreased capacity to report pain.

Behavior or responses caused by noxious stimuli in a cognitively impaired or demented individual may not necessarily reflect classic pain behaviors. In a study of 26 patients with painful conditions from a nursing home Alzheimer’s unit, Marzinski reported diverse responses to pain that were not typical of conventional pain behaviors. For example, with pain, a patient who normally moaned and rocked became quiet and withdrawn. Pain in another nonverbal patient caused rapid blinking. Other patients who normally exhibited disjointed verbalizations could, when experiencing pain, give accurate descriptions of their pain. Parmelee and Huffman and their colleagues also found that verbal pain reports by patients with dementia are accurate and valid.

The questions and suggestions in Table 5–7 can be used as a template for assessment of pain in the nonverbal or cognitively impaired patient or resident. A summary of instruments used to assess pain in nonverbal or cognitively impaired patients is found in Table 5–8. One of these instruments, the Pain Assessment in Advanced Dementia (PAINAD), is presented in Table 5–9.

Instruments Used to Assess Pain in Nonverbal or Cognitively Impaired Patients

The following are examples of pain scales and tools being used or tested in the non-verbal or cognitively impaired population.

Pain Intensity Scales

Recent research indicates that the verbal descriptor scale (VDS), the numeric rating scale (NRS), the faces pain scale (FPS), the Iowa pain thermometer (IPT), and the 21-point box pain intensity scales are reliable and valid in older adults with mild to moderate degrees of cognitive impairment. The IPT is a modified VDS that provides more options between words and is aligned with a pain thermometer to improve the conceptualization of pain. The horizontal 21-point box scale has a row of 21 boxes labeled from 0 (no pain) to 100 (pain as bad as it could be) in increments of five; respondents indicate the box that best represents their pain. Cognitively impaired older adults are able to accurately complete one

or more pain intensity scales; however, there is concern about the reliability of their short-term pain reports. Taylor & Herr recommend consideration of the FPS when repeat assessments are indicated. While the FPS is generally favored for both cognitively intact and cognitively impaired older adults, particularly minorities, it should be noted that the FPS may not clearly represent pain intensity only but may represent a broader construct “pain affect.” Because the FPS is easy to use and easily understood, it can be offered to minority older adults as an alternative if other validated tools, such as the VDS and NRS, are not usable by this population because of language barriers. Further research is needed to determine whether preference for pain intensity scales is influenced by specific cognitive level and disability, gender, age, education, race, and ethnicity/culture.

Pain Behavior Tools

Assessing pain in patients/residents who are nonverbal or cognitively impaired and are unable to verbally self-report pain presents a particular challenge to clinicians. There have been a variety of instruments that have been used by chronic pain programs to systematically observe and measure the frequency of pain behaviors, but their use has been limited in the palliative care setting. Many health care providers and researchers have attempted to develop an easy-to-use yet valid and reliable instrument for the assessment of pain in this vulnerable population (see Table 5–8). Herr and colleagues have performed an extensive and critical evaluation of many of these existing tools (conceptualization, subject/setting, reliability and validity, administration/scoring methods, strengths/weaknesses) with the intent of providing up-to-date information to clinicians and researchers. The findings from the Herr and colleagues review are available at http://prc.coh.org; it is anticipated that this web site will be updated regularly with the most current data on pain assessment tools. Brief descriptions of pain behavior tools follow.

Discomfort Scale for Dementia of the Alzheimer Type (DS–DAT).

Hurley and colleagues, based on behaviors observed by nurses, developed an objective scale for assessing discomfort in nonverbal patients with advanced Alzheimer’s disease. The investigators defined discomfort as “a negative emotional and/or physical state subject to variation in magnitude in response to internal or environmental conditions.” The negative state to which they referred could be a condition other than pain, such as anguish and suffering. After testing for reliability, a scale of 9 items was retained from an original list of 26 behavioral indicators for discomfort. Items retained were: noisy breathing, negative vocalization, absence of a look of contentment, looking sad, looking frightened, having a frown, absence of relaxed body posture, looking tense, and fidgeting. Scoring of the DS–DAT is based on evaluation of frequency, intensity, and duration of the behaviors and may be cumbersome, requiring more training and education than is feasible or realistic for clinicians in hospital or long term care settings.

Although the DS–DAT has been criticized for being too complex for routine nursing care, it has been revised and offers potential for use in the palliative care setting.

The Assessment of Discomfort in Dementia Protocol (ADD).

The ADD was developed to improve the recognition and treatment of pain and discomfort in patients with dementia who cannot report their internal states, with the added goal of decreasing inappropriate use of psychotropic medication administration. This protocol is “based upon the assumption that behaviors associated with dementia are symptoms of unmet physiologic and/or nonpharmacologic needs” (p. 193). In addition to the DS–DAT items, the ADD protocol includes more overt symptoms, such as physical aggression, crying, calling out, resisting care, and exiting behaviors. Implementation of the protocol when basic care interventions failed to ameliorate behavioral symptoms resulted in significant decreases in discomfort, significant increases in the use of pharmacologic and nonpharmacologic comfort interventions, and improved behavioral symptoms. Use of a combined assessment and treatment protocol appears promising for the palliative care setting.

Checklist of Nonverbal Pain Indicators (CNPI).

Feldt developed the CNPI specifically for cognitively impaired elders. Modified from the University of Alabama-Birmingham Pain Behavior Scale for chronic pain patients, the CNPI is a six-item tool that rates the absence or presence of the following behaviors, at rest and on movement: nonverbal vocalizations (moans, groans, sighs), facial grimaces (furrowed brow, narrowed eyes, clenched teeth), bracing (clutching or holding onto furniture or affected area), rubbing (massaging affected area), restlessness (constant or intermittent shifting of position, rocking, inability to keep still), and verbal complaint (saying “ouch,” “don’t touch me,” “that’s enough,” or cursing during movement). A summed score of the number of nonverbal pain indicators observed at rest and on movement is calculated (total possible score = 0–12). It should be noted that an increased score does not reflect actual pain severity nor does it compare to other numeric scales measuring pain. In a study of elderly hip fracture inpatients in which 60% were cognitively impaired, the CNPI demonstrated face validity and interrater reliability (93% agreement by two gerontologic nurse practitioners), although internal consistency was low (6 = .54 and .64, at rest and movement). It was also reported to be easy to use by nursing staff. Further research is needed on this tool’s validity, reliability, and appropriateness for cognitively impaired patients.

Non-Communicative Patient’s Pain Assessment Instrument (NOPPAIN).

The NOPPAIN was developed as a nursing assistant–administered instrument. Pain is observed at rest and on movement while nursing assistants perform resident care (bathing, dressing, transferring). Pain behaviors are observed and pain intensity is scored using a pain thermometer.
Pain Assessment for the Dementing Elderly (PADE).\textsuperscript{192} The PADE was designed to help caregivers assess patient/resident behavior indicating pain. PADE items (n = 24) were developed after a literature review, interviews with nursing staff, and observations of residents in a dementia unit. The PADE consists of three parts: physical (facial expressions, breathing, and posture); global (caregiver-rated pain); functional (activities of daily living).

Patient Assessment Tool in Confused Older Adults (PATCOA).\textsuperscript{193} The PATCOA was evaluated in an initial study of 116 older adults (60 to 80 years of age) undergoing orthopedic surgery.\textsuperscript{193} Patients with Alzheimer’s disease were excluded from the study. The PATCOA is an ordinal scale which includes 9 items of nonverbal pain cues rated as absent or present while the patient is at rest; higher scores indicate higher pain intensity. A vertical VAS was used in the study to meet the sensory needs of the older age group. Several nonverbal cues consistent with the CNPI\textsuperscript{144} included clenching jaws, frowning, grimacing, and vocalizations of moaning and sighing. The internal consistency reliability was below 0.70 which the investigators related to measurement of multiple dimensions of the pain experience, low interrater reliability for several nonverbal cues, and the small number of items in the tool. The study showed no significant differences between self-report of pain and demonstration of nonverbal cues with acute confusion. However, this initial study was limited by the predominance of a cognitively intact sample (only 3.5% of the patients were confused and 12% at high risk for confusion), making it too difficult to differentiate between nonverbal cues of pain from acute confusion. Further reliability and validity testing of the PATCOA is planned.

The Pain Assessment in Advanced Dementia Scale (PAINAD).\textsuperscript{194} Warden, Hurley, & Volicer\textsuperscript{194} derived the PAINAD from the behaviors and categories of the FLACC,\textsuperscript{195} a behavioral scale used to measure pain severity in postoperative children; the DS-DAT\textsuperscript{187}; and pain descriptors of dementia by experienced clinicians. The intent of the PAINAD is to simply measure pain using a 0–10 score in noncommunicative individuals. This tool, tested on Caucasian male veteran residents with advanced dementia (n = 19) who were not able to communicate their pain intensity, was compared with the DS–DAT and two VAS by trained raters/expert clinicians, and was shown to have good construct validity and reliability; internal consistency was lower than what is desired for a new scale. Future research using this tool with a more diverse population (long-term care or palliative setting) is warranted.

Pain Assessment for Seniors with Limited Ability to Communicate (PACSLAC).\textsuperscript{196} Fuchs-Lacelle and Hadjis-tavropoulos\textsuperscript{196} developed and preliminarily evaluated an observational tool to assess pain in severely demented seniors. To validate the tool, forty nurses were asked to recall patients under their care who were experiencing pain, distress, and calm, and to rate those experiences using the 60-item checklist, taking approximately 5 minutes per administration. Four subscales of the tool were derived: Social/Personality/Mood Indicators, Facial Expressions, Activity/Body Movement, and Physiological Indicators/Eating/Sleeping Changes/Vocal Behaviors. Preliminary evidence suggests that the PACSLAC can differentiate between pain and distress; scores were positively correlated with cognitive impairment level. This tool may be appropriate for use in the cognitively impaired palliative care patient. However, further research is needed on clinicians who complete the checklist while observing the patient in pain.

Abbey Pain Scale.\textsuperscript{197} A tool based on Hurley’s\textsuperscript{187} and Simon & Malabar’s\textsuperscript{200} work was developed for use with residents with end or late stage dementia unable to express their needs. Six behavioral indicators were identified and scored with three grades of severity (0 = absent through 3 = severe) for a total possible score of 18. Further testing is warranted to establish reliability and validity.

Proxy Pain Assessment in the Nonverbal or Cognitively Impaired Patient/Resident

Just as the experience of pain is subjective, “witnessing another in pain is a subjective experience.”\textsuperscript{201} Without verbal validation from the patient, the clinician must rely not only on behavioral observations but on intuition and personal judgment. It is also particularly important to elicit the opinions of the individuals closest to the patient, which are also subjective.

Nurses and other health care providers reflect the difficulty of accurately assessing pain in nonverbal or cognitively impaired patients in studies that show low concurrence between patients’ self-ratings of pain and clinicians’ ratings.\textsuperscript{202–204} Other findings are equivocal, with some studies suggesting that family caregivers or significant others accurately estimate the amount of pain cancer patients experience\textsuperscript{69} and others proposing that family caregivers overestimate patients’ pain.\textsuperscript{205–207} Brucka and colleagues\textsuperscript{208} studied relatives and the nurses who cared for 60 unresponsive, dying patients. Both were asked to rate a patient’s discomfort level, six observed behaviors (grimacing, groaning, shouting, touching or rubbing an area, purposeless movement, labored breathing), and the suspected reason for the discomfort. Although the mean levels of perceived discomfort were similar, relatives reported significantly more observed behaviors and more often indicated pain as a reason for discomfort than did the nurse caregivers. According to Cohen-Mansfield,\textsuperscript{209} relatives of cognitively impaired nursing home residents are better able to interpret facial expressions and other pain behaviors if they visit their loved ones at least once a week and have a close relationship. Additionally, higher levels of cognitive functioning were related to improved ability of relatives to assess pain and to higher levels of perceived pain.

The Edmonton Symptom Assessment System (ESAS) is a validated tool for use in the palliative care setting (Figure 5–4). It was originally tested in 101 consecutive palliative care inpatients; 83% of symptom assessments were done by nurses or patients’ relatives.\textsuperscript{210} The ESAS is a brief and reproducible scale consisting of separate visual analog or numeric scales that

evaluate nine symptoms (pain, activity, nausea, depression, anxiety, drowsiness, appetite, sensation of well-being, and shortness of breath). The tool is completed twice a day by palliative care unit patients, daily by hospice patients, and several times a week by home care patients. If patients are unable to complete the form, a space is provided for the person completing the assessment. If patients or residents are unresponsive and incapable of reporting their own pain (e.g., during the final days of life), observer judgments of pain become necessary. In this situation, the main caregiver or nurse completes the Edmonton Comfort Assessment Form (ECAF). The scores on either assessment can be transferred to a graph to present a visual display of trends in a patient’s symptoms and discomfort. Lower scores designate better symptom control (the highest possible score is 900 on the ESAS). Although the ESAS has been considered useful to display the incidence of symptoms, some investigators have found it to be impractical in patients with a poor performance status.211 To evaluate pain and other symptoms, an individualized approach may be a more appropriate practice than completing health-related checklists.

Implications for Treatment

Although pain assessment in the nonverbal or cognitively impaired patient or resident presents a challenge to clinicians, it should not pose a barrier to optimal pain management. If patients are no longer able to verbally communicate whether they are in pain or not, the best approach is to assume that their underlying disease is still painful and to continue pain interventions.212 Nonverbal patients should be empirically treated for pain if there is preexisting pain or evidence that an individual in a similar condition would experience pain.213 Likewise, palliative measures should be considered in nonverbal patients with behavior changes potentially related to pain. Studies demonstrate that pain behaviors are modified or decreased by pain interventions and adjustments in analgesia.190,200

Summary

In summary, multiple factors should be incorporated into the assessment of the pain experience. The following case examples include some of the pain assessment techniques discussed in this chapter and may prove beneficial in applying this content for nurse clinicians.

Case Study

Paul, a Hospice Patient with Pain

Paul is an 88-year-old man with prostate cancer metastatic to the bone that is unresponsive to hormonal manipulation, chemotherapy, and radiation therapy. Paul has new left hip and low back pain; a recent bone scan shows widespread metastatic disease. Paul’s past medical history includes arthritis and stroke with residual left-sided weakness. Paul has had difficulty walking due to increased pain and disuse syndrome due to his previous stroke. He recently fell and is now bedridden. It is extremely uncomfortable for him to be moved from side to side because of the pain. He also has a stage II pressure ulcer on his coccyx that seems to be worsening.

Paul describes his pain as achy, throbbing, and gnawing as he points to his left hip and lower back. He rates his persistent pain as a 4 (on a scale of 0 to 10), worsening to an 8 with movement and activity. His pain has interfered with his ability to sleep throughout the night and with his movement; his appetite has decreased significantly over the past month, and he has had some constipation. Paul’s family is concerned about his taking pain medication because of fears of dependence and side effects (constipation, sedation). Paul is a stoic man who does not openly complain about pain to his wife, daughters, nurses, or doctor. He does not want to be a burden on his family, and realizes his prostate cancer is incurable. He has accepted hospice care.

1. What type of pain is Paul experiencing?
2. How do you know he is having pain?
3. What pharmacological approaches would you suggest?
4. What nonpharmacological strategies would you incorporate into the pain management plan?
5. What other symptoms or side effects would you be concerned about?

June, a Cognitively Impaired Resident with Pain

June is an 87-year-old woman with a history of pneumonia, degenerative joint disease, osteoporosis, diabetes, Alzheimer’s dementia, and myelodysplastic disorder who has been admitted to your facility. June is extremely depressed. The certified nursing assistants caring for June report that she moans and groans when they bathe and change her (she is incontinent of bowel and bladder) and screams, “You’re so mean to me!” She often is tearful, has a sad facial expression, and is very restless.

1. What kind of pain might June be having?
2. What can be done for her pain?
3. Did she take any pain medication previously?
4. What does her family think?
5. How can her caregivers tell if the pain has been controlled?

Case Study

June

June is an 87-year-old woman with a history of pneumonia, degenerative joint disease, osteoporosis, diabetes, Alzheimer’s dementia, and myelodysplastic disorder who has been admitted to your facility. June is extremely depressed. The certified nursing assistants caring for June report that she moans and groans when they bathe and change her (she is incontinent of bowel and bladder) and screams, “You’re so mean to me!” She often is tearful, has a sad facial expression, and is very restless.

1. What kind of pain might June be having?
2. What can be done for her pain?
3. Did she take any pain medication previously?
4. What does her family think?
5. How can her caregivers tell if the pain has been controlled?

APPENDIX 5–1
Instructions for Use of the Edmonton Comfort Assessment Form (ECAF)

Title: Edmonton Comfort Assessment Form (ECAF) - Instructions for Use

Date: June 8, 1998

Approved By: Program Director

Purpose: Patient assessment is required throughout the palliative care process. The majority of patients will experience confusion and delirium before death. In these patients, who are unable to communicate, primary caregivers, and staffs input is important for assessment and for the opportunity to explain to the caregiver how to interpret the discomfort of the patient. This evaluation may decrease the caregivers concerns regarding the comfort of their family/friend.

Procedure:

1. **ECAF vs. ESAS: When to use:** All patients admitted to all the palliative programs within the Edmonton region are assessed using the ESAS. When patients reach the unresponsive state of their illness, the ESAS will be discontinued and replaced by the ECAF. If patients present with brief periods of confusion or somnolence, then expect it to be reversible. The assessment should continue with ESAS. When the patient is considered to have reached the last hours or days of life the assessment will be changed to the ECAF.

   The decision to change the assessment system will be determined by the physicians and/or team leaders in the Acute Palliative Care Unit, it will be written by the Unit Managers in the 3 hospices, by the physician or nurse consultants at the Regional Palliative Care Program, and the Referral Centre palliative care program. In Home Care, the decision to change from ESAS to ECAF will be made by the Palliative Home Care Coordinator.

2. **Frequency of Completion:** At the end of the day/evening shift in the (Acute Palliative Care Unit), day shift in the (Hospices) or the nursing visit for patients assessed at home or in the referral centres.

3. **Method of Completion:** Please note that the form has two parts.

   a) **Main Caregiver:** This part should only be completed by the caregiver that is at the bedside most of the time; at home, in hospice, or in the palliative care unit. If no caregiver is present most of the time at the bedside checkmark not applicable. If there is a caregiver, he or she should be presented with the
upper portion of the form and asked to circle the item #1 (comfort) and to check the appropriate reasons under item #2.

b) Nurse Score: The nurse will complete the form regarding behaviors. Please notice that these also have three items:
   i) Observed behavior: Rate the observed behavior according to the graph by placing an X in the appropriate box. Calculate the total score by adding the corresponding number for each X together. Maximum score is 24.
   ii) Checkmark the suspected reason(s).
   iii) Enter the global comfort assessment score from 0-10 (same as caregiver scale above).

4. After completing the form the information will be transcribed to the ECAF Graph. The ECAF Graph has the following components:

a) Date and admission day: Please notice that there is enough room for two daily assessments (Acute Palliative Care Unit). Patients admitted to the hospices will undergo one assessment a day. Patients seen by the other teams will have one assessment done on occasion of each visit.

b) Caregiver VAS (Item 1): Fill the bar up to the number across by the caregiver in the same way as we graph the results of the ESAS. If no caregiver enter N for not applicable.

c) Caregiver Reason (Item 2): Simply check the reason(s) that have been checked in the ECAF form by the caregiver.

d) Nurse Score (0-24): Write down on the space the number that results from adding each of the 6 line items for the observed behaviour (Item 1 of the Nursing Score).

e) Nurse Reason: Check the suspected reason(s) identified by the nurse during the assessment.

f) RN VAS: Enter the number of the nurse’s assessment of the level of comfort (0-10).

g) Physician VAS: Upon every visit (once a day on acute unit), on each visit in acute care, hospice and home) the physician assesses the level of comfort and enters the global comfort assessment score (0-10).
GUIDELINES FOR USING THE EDMONTON SYMPTOM ASSESSMENT SHEET  
(ESAS VISUAL ANALOGUE, NUMERICAL SCALE AND GRAPH)

1. This tool is designed to assist the patient in the assessment of his/her symptoms. Those symptoms include pain, activity, nausea, depression, anxiety, drowsiness, appetite, wellbeing and shortness of breath. The patient and family should be taught how to complete the scales. It is the patients opinion of the severity of the symptoms that is the “gold standard” for symptom assessment.

2. There are two formats for the ESAS. The first is a visual analogue scale (ESAS) that is 100mm long. The patient marks the line to indicate where the symptom is between the two extremes. (See Tool) This tool is used on the acute palliative care units, and referral hospital sites.

3. The other format, ESAS numerical is a scale from 0 to 10 where the patient circles the most appropriate number to indicate where the symptom is between the two extremes. This tool is used in all other settings, such as home care and continuing care. This tool is considered easier for a patient to complete with minimal assistance.

<table>
<thead>
<tr>
<th>No pain</th>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
<th>6</th>
<th>7</th>
<th>8</th>
<th>9</th>
<th>10</th>
<th>worst possible pain</th>
</tr>
</thead>
</table>

The circled number on the continuum is then transcribed onto the symptom assessment graph. (ESAS graph) (See #12)

4. Synonyms for words that may be difficult for the patients to comprehend include the following:

   Depression - blue or sad
   Anxiety    - nervous or restless
   Drowsy     - sleepy
   Wellbeing  - overall comfort both physical and psychological, truthfully answering the question, how are you?

5. For Home Care, during each telephone or personal contact, the ESAS scale should be completed and the values transferred to the ESAS graph. If the patient’s symptoms are in good control, and there are no predominant psychosocial issues, the ESAS can be completed 2 to 3 times a week.

In continuing care settings the ESAS should be completed daily. Referral hospital site consultants will utilize the tool in their assessment on every visit. The ESAS is completed twice (~1000h, 1800h) on the acute palliative care unit.

6. In the home, or hospice, if the patient’s symptoms are not in good control (>5/10), the nurse should be notifying the family doctor, and visiting the patient on a daily basis, until the symptoms are back within good control. (See #8)

7. If symptom management is not attained, or consultation about possible care options is needed, a consult to the Regional Palliative Care Program should occur. (Family doctor must agree). Informal consultation with the Regional program nurses and physicians can occur at any time.
8. A patient may consistently score high on an isolated symptom, and treatment has been actively pursued, until no resolution is possible. If at this point, consensus is reached between the coordinator and the family practitioner and/or consultant that a symptom cannot be modified, visits may return to their normal pattern for that patient.

9. Ideally, the patient should fill out their own assessment (ESAS). However, if there is cognitive impairment (i.e., patient’s mini-mental score below normal for their age and education) or lack of understanding on how to mark the continuum, the assessment becomes family assisted, or nurse.

10. The person who did the assessment must be identified on the symptom control graph. (ESAS graph)
   
   | P | Patient                           |
   | N | Nurse/Health Care Worker         |
   | NA| Nurse/Health Care Worker Assisted|
   | F | Family/Primary Caregiver         |

11. If the assessment is done by the nurse and she/he is unable to communicate with the patient (i.e., cognitively impaired and cognition level might be reversible) she/he assesses the following areas only: pain, activity, nausea, drowsiness, appetite and shortness of breath.

**NB:** ACTIVITY IS A PURPOSEFUL VOLUNTARY ACTION BY THE PATIENT. CONSIDER THE PATIENT NOT ACTIVE IF HE/SHE IS RESTLESS OR AGITATED

APPETITE BECOMES THE ABSENCE OR PRESENCE OF EATING

NAUSEA BECOMES THE ABSENCE OR PRESENCE OF RETCHING, VOMITING, ETC.

12. The nurse can document her assessment directly on the Symptom Assessment Graph (ESASII). She does not have to fill out the ESAS scale. The ESAS graph is kept in the patient home envelope, and a copy on the patient chart. The chart copy should be brought to the home and updated with the home copy, on each visit.

13. A patient has the right to refuse the symptom assessment or any question on it. In the event the patient refuses to do his/her own assessment, it becomes a nurse assessment (see # 10,11)

15. The ESAS is available in Cantonese, German, French and in faces, for those patients who do not read.

16. The ESASII (graph) provides an excellent clinical “picture” or “snapshot” of how a patient is feeling in various physical or psychological areas. You may see a symptom increase or decrease over time. On rare occasions, a patient may score everything as 9 or 10 out of 10. The graph looks very black and shows a picture of total pain or total suffering. A patient with this picture requires interdisciplinary support.¹

17. The Graph also contains space to add the patient’s mini mental state exam score. The “normal” box refers to the normal range for the patient, based on age and education level (see Instructions for MMSE).

18. Modified EFAT score can be entered on this form (as applicable).

19. A new assessment tool for patients who are not able to complete their own ESAS is currently being developed. (Edmonton Discomfort Assessment Tool).
Pain at the End of Life

“How much I suffered last night... there are no words to express it, only howls of pain could do so.”
—Alphonse Daudet

Key Points

- Pain is highly prevalent in palliative care, yet the majority of individuals can obtain good relief with available treatment options.
- An awareness of barriers to adequate pain care allows palliative care nurses to assess for and to plan interventions to overcome these obstacles when caring for patients. Advocacy is a critical role of the palliative care nurse.
- Assessment of pain, including a thorough history and comprehensive physical exam, guides the development of the pharmacological and nonpharmacological treatment plan.
- Pharmacological therapies include nonopioids, opioids, coanalgesics, cancer therapies, and in some cases, interventional techniques.
- Intractable pain and symptoms, although not common, must be treated aggressively. In some cases, palliative sedation may be warranted.

Prevalence of Pain

The prevalence of pain in the terminally ill varies by diagnosis and other factors. Approximately one third of persons who are actively receiving treatment for cancer and two thirds of those with advanced malignant disease experience pain.7–9 Individuals at particular risk for undertreatment include the elderly, minorities, and women.7,9 Almost three quarters of patients with advanced cancer admitted to the hospital experience pain upon admission.9 In a study of cancer patients very near the end of life, pain occurred in 54% at 4 weeks and 34% at 1 week before death.10 In other studies of patients admitted to palliative care units, pain often is the dominant symptom, along with fatigue and dyspnea.14 Children dying of cancer also are at risk for pain and suffering.11

More recently, an attempt has been made to characterize the pain experience of those with human immunodeficiency

Of the many symptoms experienced by those at the end of life, pain is one of the most common and most feared.14,2 However, this fear is largely unfounded because the majority of patients with terminal illness can obtain relief. Nurses are critical members of the palliative care team, particularly in providing pain management. The nurse’s role begins with assessment and continues through the development of a plan of care and its implementation. During this process, the nurse provides education and counsel to the patient, family, and other team members. Nurses also are critical for developing institutional policies and monitoring outcomes that ensure good pain management for all patients within their palliative care program. To provide optimal pain control, all health care professionals must understand the frequency of pain at the end of life, the barriers that prevent good management, the assessment of this syndrome, and the treatments used to provide relief.
As osteoarthritis or low back pain.20 and more likely to have existing chronic pain syndromes, such as multiple sclerosis and stroke, seen at the end of life.17–19 Furthermore, many patients in hospice and palliative care are elderly and more likely to have existing chronic pain syndromes, such as osteoarthritis or low back pain.20

Unfortunately, there has been little characterization of the pain prevalence and experience of patients with other life-threatening disorders. However, those working in palliative care are well aware that pain frequently accompanies many of the neuromuscular and cardiovascular disorders, such as multiple sclerosis and stroke, seen at the end of life.17–19 Furthermore, many patients in hospice and palliative care are elderly and more likely to have existing chronic pain syndromes, such as osteoarthritis or low back pain.20

Additional research is needed to fully characterize the frequency of pain and the type of pain syndromes seen in patients at the end of life. This information will lead to improved detection, assessment, and, ultimately, treatment. Unfortunately, pain continues to be undertreated, even when prevalence rates and syndromes are well understood. The undertreatment is largely due to barriers related to health care professionals, the system, and patients and their families.

**Barriers to Pain Relief**

Barriers to good pain relief are numerous and pervasive. Often, because of lack of education, misconceptions, or attitudinal issues, these barriers contribute to the large numbers of patients who do not get adequate pain relief.21,22 Careful examination of these barriers provides a guide for changing individual practice, as well as building an institutional plan within the palliative care program to improve pain relief (Table 6–1). Most studies address the barriers associated with cancer pain. Therefore, barriers facing individuals with other disorders commonly seen in palliative care are not well characterized. One might suggest that these individuals are affected to an even greater extent as biases may be more pronounced in those with noncancer diagnoses.

**Health Care Providers**

Fears related to opioids held by professionals lead to underuse of these analgesics. Numerous surveys have revealed that physicians, nurses, and pharmacists express concerns about addiction, tolerance, and side effects of morphine and related compounds.23 Inevitability of pain is also expressed, despite evidence to the contrary.24 Not surprisingly, lack of attention to pain and its treatment during basic education is frequently cited.24–27 Those providing care at the end of life must evaluate their own knowledge and beliefs, including cultural biases, and strive to educate themselves and colleagues.28

**Health Care Settings**

Lack of availability of opioids is pervasive, affecting not only sparsely populated rural settings but also inner-city pharmacies reluctant to carry these medications.8–11 Pain management continues to be a low priority in some health care settings, although the Joint Commission on Accreditation of Health-care Organizations (JCAHO) standards on pain management are helping to alleviate this problem.32,33 All JCAHO-certified clinical settings must evaluate their procedures to ensure that pain is appropriately assessed, treated, and documented.

**Patients and Families**

Understanding these barriers will lead the professional to better educate and better counsel patients and their families.34 Since these fears are pervasive, patients and family members or support persons should be asked if they are concerned about addiction and tolerance (often described as becoming “immune” to the drug by laypersons).35 Studies have suggested that these fears lead to undermedication and increased intensity of pain.36 Concerns about being a “good” patient or belief in the inevitability of cancer pain lead patients to hesitate in reporting pain.22,37,38 In
these studies, less educated and older patients were more likely to express these beliefs.\textsuperscript{39–41} Patients seeking active treatment may believe that admitting to pain or other symptoms may reduce their eligibility for clinical trials.

At the end of life, patients may need to rely on family members or other support persons to dispense medications. Each person’s concerns must be addressed or provision of medication may be inadequate. Studies suggest that little concordance exists between patients’ and family members’ beliefs regarding analgesics.\textsuperscript{42,43} The interdisciplinary team is essential, with nurses, social workers, chaplains, physicians, volunteers, and others providing exploration of the meaning of pain and possible barriers to good relief. Education, counseling, reframing, and spiritual support are imperative. Ersek\textsuperscript{44} provided an excellent review of the assessment and interventional approaches indicated for specific patient barriers.

\textit{Effects of Unrelied Pain}

Although many professionals and laypersons fear that opioid analgesics lead to shortened life, there is significant evidence to the contrary. Inadequate pain relief hastens death by increasing physiological stress, potentially diminishing immunocompetence, decreasing mobility, worsening proclivities toward pneumonia and thromboembolism, and increasing work of breathing and myocardial oxygen requirements.\textsuperscript{44,45} Furthermore, pain may lead to spiritual death as the individual’s quality of life is impaired.\textsuperscript{46–47} Therefore, it is the professional and ethical responsibility of clinicians to focus on and attend to adequate pain relief for their patients and to properly educate patients and their caregivers about opioid analgesic therapies.

\textit{Assessment and Common Pain Syndromes}

Comprehensive assessment of pain is imperative. This must be conducted initially, regularly throughout the treatment, and during any changes in the patient’s pain state.\textsuperscript{48} A randomized controlled trial using algorithms found that the comprehensive pain assessment integral to these algorithms contributed to reduced pain intensity scores.\textsuperscript{49} For a complete discussion of pain assessment, see Chapter 5.

\textit{Pharmacological Management of Pain in Advanced and End-Stage Disease}

A sound understanding of pharmacotherapy in the treatment of pain is of great importance in palliative care nursing. First, this knowledge allows the nurse to contribute to and fully understand the comprehensive plan of care. Thorough understanding also allows the nurse to recognize and assess medication-related adverse effects, to understand drug–drug and drug–disease interactions, and to educate patients and caregivers regarding appropriate medication usage. This will assure a comfortable process of dying for the well-being of the patient and for the sake of those in attendance.

This section provides an overview of the most commonly used agents and some of the newer pharmaceutical agents available in the United States for the treatment of unremitting and recurrent pain associated with advanced disease. The intent of this section is to arm the reader with a fundamental and practical understanding of the medications that are (or should be) available in most contemporary care settings, emphasizing those therapies for which there is clear and convincing evidence of efficacy. For an extensive review of mechanisms of pain and analgesia, pharmacological principles of analgesics, and more-detailed lists of all drugs used for pain control throughout the world, the reader is referred to recent comprehensive reviews.\textsuperscript{13,50–57} Since patients or family members are not always aware of the names of their medications, or they may bring pills to the hospital or clinic that are not in their original bottles, several web-based resources provide pictures that can assist the nurse in identifying the current analgesic regimen. These can be found at http://www.healthsquare.com/drugmain.htm or http://www.drugs.com.

\textbf{Nonopioid Analgesics}

\textbf{Acetaminophen}

Acetaminophen has been determined to be one of the safest analgesics for long-term use in the management of mild pain or as a supplement in the management of more intense pain syndromes. It is especially useful in the management of nonspecific musculoskeletal pains or pain associated with osteoarthritis, but acetaminophen (also abbreviated as APAP) should be considered an adjunct to any chronic pain regimen. It is often forgotten or overlooked when severe pain is being treated, so a reminder of its value as a “coanalgesic” is warranted. However, acetaminophen’s limited antiinflammatory effect should be considered when selecting a nonopioid. Reduced doses or avoidance of acetaminophen is recommended in the face of renal insufficiency or liver failure, and particularly in individuals with significant alcohol use.\textsuperscript{58,59}

\textbf{Nonsteroidal Antiinflammatory Drugs}

Nonsteroidal antiinflammatory drugs (NSAIDs) affect analgesia by reducing the biosynthesis of prostaglandins, thereby inhibiting the cascade of inflammatory events that cause, amplify, or maintain nociception. These agents also appear to reduce pain by influences on the peripheral or central nervous system independent of their antiinflammatory mechanism of action. This secondary mode of analgesic efficacy is poorly understood. The “classic” NSAIDs (e.g., aspirin or ibuprofen) are relatively nonselective in their inhibitory effects on the enzymes that convert arachidonic acid to prostaglandins.\textsuperscript{40} As
a result, gastrointestinal (GI) ulceration, renal dysfunction, and impaired platelet aggregation are common.\textsuperscript{61,62} The cyclooxygenase-2 (COX-2) enzymatic pathway is induced by tissue injury or other inflammation-inducing conditions.\textsuperscript{63} It is for this reason that there appears to be less risk of GI bleeding with short-term use of the COX-2 selective NSAIDs.\textsuperscript{64} However, although several studies demonstrate prolonged GI-sparing effects\textsuperscript{65}, others suggest that these benefits may not extend beyond 6 to 12 months, and there may be a risk of cardiovascular events with prolonged COX-2 selective NSAID use.\textsuperscript{66–68} Additionally, because there is cross-sensitivity, patients allergic to sulfa-containing drugs should not be given celecoxib (Table 6–2).

The NSAIDs, as a class, are very useful in the treatment of many pain conditions mediated by inflammation, including those caused by cancer.\textsuperscript{61,70} There are insufficient data to determine whether the newly available COX-2 agents have any specific advantages over the nonselective NSAIDs in the management of pain due to conditions such as metastatic bone pain. The NSAIDs do offer the potential advantage of causing minimal nausea, constipation, sedation, or other effects on mental functioning, although there is evidence that short-term memory in older patients can be impaired by them.\textsuperscript{71} Therefore, depending on the cause of pain, NSAIDs may be useful for moderate to severe pain control, either alone or as an adjunct to opioid analgesic therapy. The addition of NSAIDs to opioids has the benefit of potentially allowing the reduction of the opioid dose when sedation, obtundation, confusion, dizziness, or other central nervous system effects of opioid analgesic therapy alone become burdensome.\textsuperscript{72} As with acetaminophen, decreased renal function and liver failure are relative contraindications for NSAID use. Similarly, platelet dysfunction or other potential bleeding disorders contraindicate use of the nonselective NSAIDs due to their inhibitory effects on platelet aggregation, with resultant prolonged bleeding time. Proton pump inhibitors can be given to prevent GI bleeding.\textsuperscript{73}

### Opioid Analgesics

As a pharmacological class, the opioid analgesics represent the most useful agents for the treatment of pain associated with advanced disease. The opioids are nonspecific insofar as they decrease pain signal transmission and perception throughout the nervous system, regardless of the pathophysiology of the pain.\textsuperscript{74} Moderate to severe pain is the main clinical indication for the opioid analogesics. Despite past beliefs that opioids were ineffective for neuropathic pain, these agents have been found to be useful in the treatment of this complex pain syndrome.\textsuperscript{75} Other indications for opioid use include the treatment of dyspnea, use as an anesthetic adjunct, and as a form of prophylactic therapy in the treatment of psychological dependence to opioids (e.g., methadone maintenance for those with a history of heroin abuse).\textsuperscript{76,77}

The only absolute contraindication to the use of an opioid is a history of a hypersensitivity reaction (rash, wheezing,

edema). Allergic reactions are almost exclusively limited to the morphine derivatives. In the rare event that a patient describes a true allergic reaction, one might begin therapy with a low dose of a short-acting synthetic opioid (e.g., IV fentanyl) or try an intradermal injection as a test dose. The rationale for using a synthetic opioid (preferably one without dyes or preservatives since these can cause allergic reactions) is that the prevalence of allergic reactions is much lower. If the patient does develop a reaction, using a low dose of a short-acting opioid will produce a reduced response for a shorter period of time when compared to long-acting preparations.

Because misunderstandings lead to undertreatment, it is incumbent upon all clinicians involved in the care of patients with chronic pain to clearly understand and differentiate the clinical conditions of tolerance, physical dependence, addiction, pseudoaddiction, and pseudotolerance (Table 6–3).

It is also critically important for clinicians who are involved in patient care to be aware that titration of opioid analgesics to affect pain relief is rarely associated with induced respiratory depression and iatrogenic death.\(^78,79\) In fact, the most compelling evidence suggests that inadequate pain relief hastens death by increasing physiological stress, decreasing immuno-

Adapted from references 223, 224.

In a study of patients with advanced cancer, no reliable predictors for opioid dose were identified.\(^9\) There is significant inter- and intraindividual variation in clinical responses to the various opioids, so in most cases, a dose-titration approach should be viewed as the best means of optimizing care. This implies that close follow-up is required to determine when clinical end points have been reached. Furthermore, idiosyncratic responses may require trials of different agents to determine the most effective drug and route of delivery for any given patient. Table 6–4 lists more specific suggestions regarding optimal use of opioids.

Another factor that needs to be continually considered with opioid analgesics is the potential to accumulate toxic metabolites, especially in the face of decreasing drug clearance and elimination as disease progresses and organ function deteriorates.\(^81\) Due to its neurotoxic metabolite, normeperidine, meperidine use is specifically discouraged for chronic pain management.\(^82\) Propoxyphene (e.g., Darvocet N-100) also is discouraged for use in palliative care due to the active metabolite, norpropoxyphene, its weak analgesic efficacy, and the significant acetaminophen dose found in some formulations.\(^48\) As well, the mixed agonist–antagonist agents, typified by butorphanol, nalbuphine, and pentazocine, are not recommended for the treatment of chronic pain. They have limited efficacy, and their use may cause an acute abstinence syndrome in patients who are otherwise using pure agonist opioid analgesics.\(^57\)

Morphine

Morphine is most often considered the “gold standard” of opioid analgesics and is used as a measure for dose equivalence (Table 6–5).\(^40\) Although some patients cannot tolerate morphine due to itching, headache, dysphoria, or other adverse effects, common initial dosing effects such as sedation and nausea often resolve within a few days.\(^57\) In fact, one should anticipate these adverse effects, especially constipation, nausea, and sedation, and prevent or treat appropriately (see below). One metabolite of morphine, morphine-3-glucuronide (M3G) is active and may contribute to myoclonus, seizures and hyperalgesia (increasing pain), particularly when patients cannot clear the metabolite due to renal impairment.\(^83,84\) Side effects and metabolic effects can be differentiated by the time course. Side effects generally occur soon after the drug has had time to absorb, whereas there usually is a delay in metabolite-induced effects by several days. If adverse effects exceed the analgesic benefit of the drug, convert to an equianalgesic dose of a different opioid. Because cross-tolerance is incomplete, reduce the calculated dose by one third to one half and titrate upward.
Symptom Assessment and Management

**Table 6–4**
Guidelines for the Use of Opioids

Clinical studies and experience suggest that adherence to some basic precepts will help optimize care of patients who require opioid analgesic therapy for pain control:

- Intramuscular administration is highly discouraged except in “pain emergency” states when nothing else is available. (Subcutaneous delivery is almost always an alternative.)
- Noninvasive drug delivery systems that “bypass” the enteral route (e.g., the transdermal and the oral transmucosal routes for delivery of fentanyl for treatment of continuous pain and breakthrough pain, respectively) may obviate the necessity to use parenteral routes for pain control in some patients who cannot take medications orally or rectally.
- Anticipation, prevention, and treatment of sedation, constipation, nausea, psychotomimetic effects, and myoclonus should be part of every care plan for patients being treated with opioid analgesics.
- Changing from one opioid to another or one route to another is often necessary, so facility with this process is an absolute necessity. Remember the following points:
  - Incomplete cross-tolerance occurs, leading to decreased requirements of a newly prescribed opioid.
  - Use morphine equivalents as a “common denominator” for all dose conversions in order to avoid errors.

*Footnotes:
1. Dose conversion should be closely monitored since incomplete cross-tolerance may occur.
2. Available in continuous and sustained-release pills and capsules, formulated to last 12 or 24 hours. Interindividual variation in duration of analgesic effect is not uncommon, signaling the need to increase the dose or shorten the dose interval.
3. Available as a continuous-release formulation lasting 24 hours.
4. Also available in transdermal and oral transmucosal forms, see package insert materials for dose recommendations. OTFC = oral transmucosal fentanyl citrate.
5. Available in several continuous-release doses, formulated to last 12 hours. Interindividual variation in duration of analgesic effect is not uncommon, signaling the need to increase the dose or shorten the dose interval.
6. Fentanyl 100 mcg patch = 4 mg IV morphine/h.

Adapted from References 48, 97, 98, 105, 107, 117.

Based on the patient’s pain intensity scores (see Chapter 18 for more information on the neurotoxicity of opioids). The 24-hour, long-acting morphine capsule can be broken open and the “sprinkles” placed in applesauce or other soft food. Morphine’s bitter taste may be prohibitive, especially if “immediate-release” tablets are left in the mouth to dissolve. When patients have dysphagia, several options are available.
capabilities are more significantly limited. Transmucosal uptake of morphine is slow and unpredictable due to its hydrophilic chemical nature. In fact, most of the analgesic effect of a morphine tablet or liquid placed buccally or sublingually is due to drug trickling down the throat and the resultant absorption through the GI tract. Furthermore, again due to the hydrophilic nature of morphine, creams and patches that contain morphine provide little if any analgesic effect. Another useful route of administration when oral delivery is unreasonable is the rectal route. Commercially prepared suppositories, compounded suppositories, or microenemas can be used to deliver the drug into the rectum or stoma. Sustained-release morphine tablets have been used rectally, with resultant delayed time to peak plasma level and approximately 90% of the bioavailability achieved by oral administration.

Fentanyl

Fentanyl is a highly lipid soluble opioid that has been administered parenterally, spinally, transdermally, transmucosally, and by nebulizer for the management of dyspnea. Fentanyl is a highly lipid soluble opioid that has been administered parenterally, spinally, transdermally, transmucosally, and by nebulizer for the management of dyspnea. Fentanyl is a highly lipid soluble opioid that has been administered parenterally, spinally, transdermally, transmucosally, and by nebulizer for the management of dyspnea. Fentanyl is a highly lipid soluble opioid that has been administered parenterally, spinally, transdermally, transmucosally, and by nebulizer for the management of dyspnea. Fentanyl is a highly lipid soluble opioid that has been administered parenterally, spinally, transdermally, transmucosally, and by nebulizer for the management of dyspnea. Fentanyl is a highly lipid soluble opioid that has been administered parenterally, spinally, transdermally, transmucosally, and by nebulizer for the management of dyspnea. Fentanyl is a highly lipid soluble opioid that has been administered parenterally, spinally, transdermally, transmucosally, and by nebulizer for the management of dyspnea.

Transdermal Fentanyl. Transdermal fentanyl (Duragesic®), often called the fentanyl patch, is particularly useful when patients cannot swallow, do not remember to take medications, or have adverse effects to other opioids. Opioid-naive patients should start with a 25-mcg/h patch (currently the lowest available dose) after evaluation of effects with immediate-release opioids (Table 6–6). Patients should be monitored by a responsible caregiver for the first 24 to 48 hours of therapy until steady-state blood levels are attained. Fever, diaphoresis, cachexia, morbid obesity, and ascites may have a significant impact on the absorption, predictability of blood levels, and clinical effects of transdermal fentanyl; thus, this form of administration may not be appropriate in those conditions. The specific effects of body mass and temperature on absorption have not been studied. Some believe the changes in fat stores (seen with cachexia) alter the fat depot needed for absorption of this lipid-soluble compound. There is some suggestion that transdermal fentanyl may produce less constipation when compared to long-acting morphine. Further study is needed to confirm these findings.

Some patients experience decreased analgesic effects after only 48 hours of applying a new patch; this should be accommodated by determining if a higher dose is tolerated with increased duration of effect or a more frequent (q 48 h) patch change should be scheduled. As with all long-acting preparations, breakthrough pain medications should be made available to patients using continuous-release opioids such as the fentanyl patch. Several reports have documented the safe and effective use of subcutaneous fentanyl when the transdermal approach could no longer provide relief or side effects occurred with other opioids. However, parenteral fentanyl is commercially available in a 50-mcg/mL concentration. Higher doses may preclude the subcutaneous route. When this occurs, the intravenous (IV) route is warranted.

Oral Transmucosal Fentanyl Citrate. Oral transmucosal fentanyl citrate (OTFC or Actiq) is composed of fentanyl on an applicator that patients rub against the oral mucosa to provide rapid absorption of the drug. This formulation of fentanyl is particularly useful for breakthrough pain, described later in this chapter. One example of OTFC use would be pain relief of rapid onset or during a brief but painful dressing change. Adults should start with the 200-mcg dose and monitor efficacy, advancing to higher dose units as needed. Clinicians must be aware that, unlike other breakthrough pain drugs, the around-the-clock dose of opioid does not predict the effective dose of OTFC. Pain relief can usually be expected in about 5 minutes after beginning use. Patients should use OTFC over a period of 15 minutes because too-rapid use will result in more of the agent being swallowed rather than being absorbed transmucosally. Any remaining partial units should be disposed.

### Table 6–6

**Fentanyl Patch Instructions to Patients and Caregivers**

1. Place patch on the upper body in a clean, dry, hairless area (clip hair, do not shave).
2. Choose a different site when placing a new patch, then remove the old patch.
3. If a skin reaction consistently occurs despite site rotation, spray inhaled steroid (intended for inhalational use in asthma) over the area, let dry and apply patch (steroid creams prevent adherence of the patch).
4. Remove the old patch or patches and fold sticky surfaces together, then flush down the toilet.
5. Wash hands after handling patches.
6. All unused patches (patient discontinued use or deceased) should be removed from wrappers, folded in half with sticky surfaces together, and flushed down the toilet.

Adapted from References 90, 92.
of by placing under hot water or inserting the unit in a child-resistant temporary storage bottle provided when the drug is first dispensed.

**Oxycodone**

Oxycodone is a synthetic opioid available in a long-acting formulation (OxyContin, generic long-acting oxycodone), as well as immediate-release tablets (alone or with acetaminophen) and liquid. It is approximately as lipid soluble as morphine, but has better oral absorption. The half-life of oxycodone is approximately 20–30:30 of oral morphine. Side effects appear to be similar to those experienced with morphine; however, one study comparing these two long-acting formulations in persons with advanced cancer found that oxycodone produced less nausea and vomiting. Despite significant media attention to OxyContin and its role in opioid abuse, it does not appear to be inherently “more addicting” than other opioids used in palliative care. Because of this attention, however, several states have restricted the number of tablets that will be distributed to an individual per month.

**Methadone**

Methadone has several characteristics that make it useful in the management of severe, chronic pain. The half-life of 24 to 36 hours or longer allows prolonged dosing intervals. Methadone may also bind as an antagonist to the N-methyl-D-aspartate (NMDA) receptor, believed to be of particular benefit in neuropathic pain. Furthermore, methadone is much less costly than comparable doses of proprietary continuous-release formulations, making it potentially more available for patients without sufficient financial resources for more costly drugs.

Despite these advantages, much is unknown about the appropriate dosing ratio between methadone and morphine, as well as the safest and most effective time course for conversion from another opioid to methadone. Early studies suggested the ratio might be 1:1, and this appears to be true for individuals without recent prior exposure to opioids. Newer data suggest the dose ratio increases as the previous dose of oral opioid equivalents increases. (Table 6–7) Furthermore, although the long half-life is an advantage, it also increases the potential for drug accumulation before achieving steady-state blood levels, putting patients at risk for oversedation and respiratory depression. This might occur after 2 to 5 days of treatment with methadone. Close monitoring of these potentially adverse or even life-threatening effects is required. Myoclonus has been reported with methadone use. Finally, recent studies suggest high doses of methadone may lead to QT wave changes (also called torsade de pointes), although it is not clear whether this is due to the methadone or to prescribing the parenteral formulation.

Methadone is metabolized primarily by CYP3A4, but also by CYP2D6 and CYP3A2. As a result, drugs that induce CYP enzymes accelerate the metabolism of methadone, resulting in reduced serum levels of the drug. This may be demonstrated clinically by shortened analgesic periods or reduced overall pain relief. Examples of these drugs often used in palliative care include several antiretroviral agents, dexamethasone, azole antifungals, and many other medications that are metabolized by CYP3A4.

*Morphine: methadone
carbamazepine, phenytoin, and barbiturates. Drugs that inhibit CYP enzymes slow methadone metabolism, potentially leading to sedation and respiratory depression. These include ketoconazole, omeprazole, and SSRI antidepressants such as fluoxetine, paroxetine, and sertraline.

Patients currently receiving methadone as part of a maintenance program for addictive disease will have developed cross tolerance to the opioids, and as a result, will require higher doses than naive patients. Prescribing methadone for addictive disease requires a special license in the United States. Therefore, prescriptions provided for methadone to manage pain in palliative care should include the statement “for pain.”

Hydromorphone

Hydromorphone (Dilaudid) is a useful alternative when synthetic opioids provide an advantage. It is available in oral tablets, liquids, suppositories, and parenteral formulations, and it is now also available in the United States in a long-acting formulation. As a synthetic opioid, hydromorphone provides an advantage when patients have true allergic responses to morphine, or when inadequate pain control or intolerable side effects occur. Recent experience suggests that the metabolite hydromorphone-3-glucuronide (H3G) may lead to the same opioid neurotoxicity seen with morphine metabolites: myoclonus, hyperalgesia, and seizures. This is of particular risk in persons with renal dysfunction.

Other Opioids

Codeine, hydrocodone, levorphanol, oxymorphone and transmoral are other opioids available in the United States for treatment of pain. Their equianalgesic comparisons are included in Table 6–5.

Preventing and Treating Adverse Effects of Opioid Analgesics

Constipation. Patients in palliative care frequently experience constipation, in part due to opioid therapy. Always begin a prophylactic bowel regimen when commencing opioid analgesic therapy. Avoid bulking agents (e.g., psyllium) since these tend to cause a larger, bulkier stool, increasing desiccation time in the large bowel. Furthermore, debilitated patients can rarely take in sufficient fluid to facilitate the action of bulking agents. Fluid intake should be encouraged whenever feasible. Senna tea and fruits may be of use. For a more comprehensive review of bowel management, refer to Chapter 11.

Sedation. Excessive sedation may occur with the initial doses of opioids. If sedation persists after 24 to 48 hours and other correctable causes have been identified and treated if possible, the use of psychostimulants may be beneficial. These include dextroamphetamine 2.5 to 5 mg PO q morning and midday or methylphenidate 5 to 10 mg PO q morning and 2.5 to 5 mg midday (although higher doses are frequently used). Adjust both the dose and timing to prevent nocturnal insomnia and monitor for undesirable psychotomimetic effects (such as agitation, hallucinations, and irritability). Interestingly,
in a recent study, as-needed dosing of methylphenidate in cancer patients did not result in sleep disturbances or agitation, even though most subjects took doses in the afternoon and evening. Modafinil, a newer agent approved to manage narcolepsy, has been reported to relieve opioid-induced sedation with once-daily dosing.

Respiratory Depression. Respiratory depression is rarely a clinically significant problem for opioid-tolerant patients in pain. When respiratory depression occurs in a patient with advanced disease, the cause is usually multifactorial. Therefore, other factors beyond opioids need to be assessed, although opioids are frequently blamed for the reduced respirations. When undesired depressed consciousness occurs along with a respiratory rate less than 8/min or hypoxemia (O2 saturation < 90%) associated with opioid use, cautious and slow titration of naloxone should be instituted. Excessive administration may cause abrupt opioid reversal with pain and autonomic crisis. Dilute 1 ampule of naloxone (0.4 mg/mL) in 10 mL of injectable saline (final concentration 40 mcg/mL) and inject 1 mL every 2 to 3 minutes while closely monitoring the level of consciousness and respiratory rate. Because the duration of effect of naloxone is approximately 30 minutes, the depressant effects of the opioid will recur at 30 minutes and persist until the plasma levels decline (often 4 or more hours) or until the next dose of naloxone is administered.

Nausea and Vomiting. Nausea and vomiting are common with opioids due to activation of the chemoreceptor trigger zone in the medulla, vestibular sensitivity, and delayed gastric emptying, but habituation occurs in most cases within several days. Assess for other treatable causes. In severe cases or when nausea and vomiting are not self-limited, pharmacotherapy is indicated. The doses of nausea-relieving medications and antiemetics listed below are to be used initially but can be increased as required. See Chapter 9 for a thorough discussion of the assessment and treatment of nausea and vomiting.

Myoclonus. Myoclonic jerking occurs more commonly with high-dose opioid therapy. If this should develop, switch to an alternate opioid, especially if using morphine, since evidence suggests this symptom is associated with metabolite accumulation, particularly in the face of renal dysfunction. A lower relative dose of the substituted drug may be possible, due to incomplete cross-tolerance, which might result in decreased myoclonus. Clonazepam 0.5 to 1 mg PO q 6 to 8 hours, to be increased as needed and tolerated, may be useful in treating myoclonus in patients who are still alert, able to communicate, and take oral preparations. Lorazepam can be given sublingually if the patient is unable to swallow. Otherwise, parenteral administration of diazepam is indicated if symptoms are distressing. Grand mal seizures associated with high-dose parenteral opioid infusions have been reported and may be due to preservatives in the solution. Preservative-free solutions should be used when administering high-dose infusions. (See Chapter 18 for more specific information).

Pruritus. Pruritus appears to be most common with morphine, in part due to histamine release, but can occur with most opioids. Fentanyl and oxymorphone may be less likely to cause histamine release. Most antipruritus therapies cause sedation, so this side effect must be viewed by the patient as an acceptable trade-off. Antihistamines (such as diphenhydramine) are the most common first-line approach to this opioid-induced symptom when treatment is indicated. Ondansetron has been reported to be effective in relieving opioid-induced pruritus, but no randomized controlled studies exist.

Coanalgesics

A wide variety of nonopioid medications from several pharmacological classes have been demonstrated to reduce pain caused by various pathological conditions (Table 6–8). As a group, these drugs have been called analgesic 'adjuvants,' but this is something of a misnomer since they often reduce pain when used alone. However, under most circumstances, when these drugs are indicated for the treatment of severe neuropathic pain or bone pain, opioid analgesics are used concomitantly to provide adequate pain relief.

Antidepressants

The mechanism of the analgesic effect of tricyclic antidepressants appears to be related to inhibition of norepinephrine and serotonin. Despite the absence of positive controlled clinical trials in cancer pain or other palliative care pain conditions, the tricyclic antidepressants are generally believed to provide relief from neuropathic pain. A recent consensus panel listed this category as one of five first-line therapies for neuropathic pain. Side effects often limit the use of these agents in palliative care. Cardiac arrhythmias, conduction abnormalities, narrow-angle glaucoma, and clinically significant prostatic hyperplasia are relative contraindications to the tricyclic antidepressants. The delay in onset of pain relief, from days to weeks, may preclude the use of these agents for pain relief in end-of-life care. However, their sleep-enhancing and mood-elevating effects may be of benefit. A newer, atypical antidepressant, venlafaxine, has been shown to reduce neuropathy associated with cisplatin-induced neuropathy and following treatment for breast cancer.

Anticonvulsants

The older anticonvulsants, such as carbamazepine and clonazepam, relieve pain by blocking sodium channels. Often referred to as membrane stabilizers, these compounds are very useful in the treatment of neuropathic pain, especially those with episodic, lancinating qualities. Gabapentin is believed to have several different mechanisms of action, including having
NMDA antagonist and other analgesic activities. The analgesic doses of gabapentin reported to relieve pain in non-end-of-life pain conditions ranged from 900 to 3600 mg/day in divided doses. A common reason for inadequate relief is failure to titrate upward after prescribing the usual starting dose of 100 mg po three times daily. Additional evidence supports the use of gabapentin in neuropathic pain syndromes seen in palliative care, such as thalamic pain, pain due to spinal cord injury, cancer pain, along with restless leg syndrome. Withdrawal from gabapentin should be gradual to prevent possible seizures. Other anticonvulsants have been used with success in treating neuropathies, including lamotrigine, levetiracetam, tiagabine, topiramate, and zonisamide, yet no randomized controlled clinical trials are currently available.

Corticosteroids
Corticosteroids inhibit prostaglandin synthesis and reduce edema surrounding neural tissues. This category of drug is particularly useful for neuropathic pain syndromes, including plexopathies and pain associated with stretching of the liver capsule due to metastases. Corticosteroids are also highly effective for treating bone pain due to their anti-inflammatory effects, as well as relieving malignant intestinal obstruction. Dexamethasone produces the least amount of mineralocorticoid effect, leading to reduced potential for Cushing's syndrome. Dexamethasone is available in oral, IV, subcutaneous, and epidural formulations. The standard dose is 16 to 24 mg/day and can be administered once daily due to the long half-life of this drug. Doses as high as 100 mg may...
be given with severe pain crises. IV bolus doses should be pushed slowly, to prevent uncomfortable perineal burning and itching.

Local Anesthetics

Local anesthetics work in a manner similar to the older anticonvulsants, by inhibiting the movement of ions across the neural membrane. They are useful for relieving neuropathic pain. Local anesthetics can be given orally, topically, intravenously, subcutaneously, or spinally. Mexiletine has been reported to be useful when anticonvulsants and other adjuvant therapies have failed. Doses start at 150 mg/day and increase to levels as high as 900 mg/day in divided doses. Local anesthetic gels and patches have been used to prevent the pain associated with needlestick and other minor procedures. Both gel and patch (Lidoderm) versions of lidocaine have been shown to reduce the pain of postherpetic neuropathy. IV lidocaine at 1 to 5 mg/kg (maximum 500 mg) administered over 1 hour, followed by a continuous infusion of 1 to 2 mg/kg/hour has been reported to reduce intractable neuropathic pain in patients in inpatient palliative care and home hospice settings. Epidural or intrathecal lidocaine or bupivacaine delivered with an opioid can reduce neuropathic pain.

N-Methyl-d-Aspartate Antagonists

Antagonists to NMDA are believed to block the binding of excitatory amino acids, such as glutamate, in the spinal cord. Ketamine, a dissociative anesthetic, is believed to relieve severe neuropathic pain by blocking NMDA receptors (see the section ‘Pain Crisis,’ below). A recent Cochrane review found insufficient trials conducted to determine safety and efficacy in cancer pain. Routine use often is limited by cognitive changes and other adverse effects. Oral compounds containing dextromethorphan have been tested. Unfortunately, dextromethorphan was ineffective at relieving cancer pain.

Bisphosphonates

Bisphosphonates inhibit osteoclast-mediated bone resorption and alleviate pain related to metastatic bone disease and multiple myeloma. Pamidronate disodium reduces pain, hypercalcemia, and skeletal morbidity associated with breast cancer and multiple myeloma. Dosing is generally repeated every 4 weeks and the analgesic effects occur in 2 to 4 weeks. Interestingly, a recent randomized, controlled trial of pamidronate in men experiencing pain due to prostate cancer failed to demonstrate any benefit. Zoledronic acid is a newer bisphosphonate that has been shown to relieve pain due to metastatic bone disease. It is somewhat more convenient because it can be infused over a shorter duration of time. Clodronate and sodium etidronate appear to provide little or no analgesia.

Calcitonin

Subcutaneous calcitonin may be effective in the relief of neuropathic or bone pain, although studies are inconclusive. The nasal form of this drug may be more acceptable in end-of-life care when other therapies are ineffective. Usual doses are 100 to 200 IU/day subcutaneously or nasally.

Radiation Therapy and Radiopharmaceuticals

Radiotherapy can be enormously beneficial in relieving pain due to bone metastases or other lesions. In many cases, single-fraction external beam therapy can be used to facilitate treatment in debilitated patients. Goals of treatment should be clearly articulated so that patients and family members understand the role of this therapy. Radiolabeled agents such as strontium-89 and samarium-153 have been shown to be effective at reducing metastatic bone pain. Thrombocytopenia and leukopenia are relative contraindications since strontium-89 causes thrombocytopenia in as many as 33% of those treated and leukopenia up to 10%. Because of the delayed onset and timing of peak effect, only those patients with a projected life span of greater than 3 months should be considered for treatment. Patients should be advised that a transitory pain flare is reported by as many as 10% of individuals treated, and additional analgesics should be provided in anticipation.

Chemotherapy

Palliative chemotherapy is the use of antitumor therapy to relieve symptoms associated with malignancy. Patient goals, performance status, sensitivity of the tumor, and potential toxicities must be considered. Examples of symptoms that may improve with chemotherapy include hormonal therapy in breast cancer to relieve chest wall pain due to tumor ulceration, or chemotherapy in lung cancer to relieve dyspnea.

Other Adjunct Analgesics

Topical capsaicin is believed to relieve pain by inhibiting the release of substance P. This compound has been shown to be useful in relieving pain associated with postmastectomy syndrome, postherpetic neuralgia, and postsurgical neuropathic pain in cancer. A burning sensation experienced by patients is a common reason for discontinuing therapy.

Baclofen is useful in the relief of spasm-associated pain. Doses begin at 10 mg/day, increasing every few days. A generalized feeling of weakness and confusion or hallucinations often occurs with doses above 60 mg/day. Intrathecal baclofen has been used to treat spasticity and resulting pain, primarily due to multiple sclerosis and spinal cord injury, although a case report describes relief from pain due to spinal cord injury.

Calcium channel blockers are believed to provide pain relief by preventing conduction. Nifedipine 10 mg orally may be useful to relieve ischemic or neuropathic pain syndromes.
Interventional Therapies

In addition to previously discussed spinal administration of analgesics, interventional therapies to relieve pain at end of life can be beneficial, including nerve blocks, vertebroplasty, radiofrequency ablation of painful metastases, procedures to drain painful effusions and other techniques. Few of these procedures have undergone controlled clinical studies. One technique, the celiac plexus block, has been shown to be superior to morphine in patients with pain due to unresectable pancreatic cancer. A complete review of these procedures can be found in a variety of sources. Choosing one of these techniques is dependent upon the availability of experts in this area who understand the special needs of palliative care patients, the patient's ability to undergo the procedure, and the patient's and family's goals of care.

Nonpharmacological Therapies

Nondrug therapies, including cognitive–behavioral techniques and physical measures, can serve as adjuncts to analgesics in the palliative care setting. This is not to suggest that when these therapies work the pain is of psychological origin. The patient’s and caregivers' abilities to participate must be considered when selecting one of these therapies, including their fatigue level, interest, cognition, and other factors.

Difficult Pain Syndromes

The above therapies provide relief for the majority of patients (Table 6–9). Unfortunately, complex pain syndromes may require additional measures. These syndromes

These basic guidelines and considerations will optimize the pharmacologic management of all patients with pain, particularly those in the palliative care setting.

Adapted from References 48, 51, 223.
include breakthrough pain, pain crises, and pain control in the patient with a past or current history of substance abuse.

**Breakthrough Pain**

Intermittent episodes of moderate to severe pain that occur in spite of control of baseline continuous pain are common in patients with advanced disease. Studies suggest that although breakthrough pain in cancer patients at home is common, short-acting analgesics are frequently not provided and patients do not take as much as is allowed. Mostly described in cancer patients, there is evidence that patients with other pain-producing and life-limiting diseases commonly experience breakthrough pains a few times a day, lasting moments to many minutes. A recent prospective study of patients with noncancer diagnoses at end of life experienced an average of 5 breakthrough episodes per day (range 1−13), with 56% of these episodes occurring without any warning. The risk of increasing the around-the-clock or continuous-release analgesic dose to cover breakthrough pains is that of increasing undesirable side effects, especially sedation, once the more short-lived, episodic breakthrough pain has remitted. Guidelines for categorizing, assessing, and managing breakthrough pain are described below:

**Incident Pain.** Incident pain is predictably elicited by specific activities. Use a rapid-onset, short-duration analgesic formulation in anticipation of pain-eliciting activities or events. Use the same drug that the patient is taking for baseline pain relief for incident pain whenever possible. In 1998, OTFC was approved specifically for this indication in cancer patients. Clinical experience is being gained on its efficacy in other clinical situations. Adjust and titrate the breakthrough pain medication dose to the severity of anticipated pain or the intensity and duration of the pain-producing event. Past experience will serve as the best prescriptive guide.

**Spontaneous Pain.** Spontaneous pain is unpredictable and not temporally associated with any activity or event. These pains are more challenging to control. The use of adjuvants for neuropathic pains may help to diminish the frequency and severity of these types of pain (see Table 6–8). Otherwise, immediate treatment with a potent, rapid-onset opioid analgesic is indicated.

**End-of-Dose Failure.** End-of-dose failure describes pain that occurs toward the end of the usual dosing interval of a regularly scheduled analgesic. This results from declining blood levels of the around-the-clock analgesic before administration or uptake of the next scheduled dose. Appropriate questioning and use of pain diaries will assure rapid diagnosis of end-of-dose failure. Increasing the dose of around-the-clock medication or shortening the dose interval to match the onset of this type of breakthrough pain should remedy the problem. For instance, a patient who is taking continuous-release morphine every 12 hours and whose pain “breaks through” after about 8 to 10 hours is experiencing end-of-dose failure. The dose should be increased by 25% to 50%, if this is tolerated, or the dosing interval should be increased to every 8 hours.

**Bone Pain**

Pain due to bone metastasis or pathological fractures can include extremely painful breakthrough pain, often associated with movement, along with periods of somnolence when the patient is at rest. In one study of cancer patients admitted to an inpatient hospice, 93% had breakthrough pain, with 72% of the episodes related to movement or weight bearing. Treatment of bone pain includes the use of corticosteroids, bisphosphonates if indicated, radiotherapy or radionuclides if consistent with the goals of care, long-acting opioids, along with short-acting opioids for the periods of increasing pain. Vertebroplasty may stabilize the vertebrae if tumor invasion leads to instability.

**Pain Crisis**

Most nociceptive (i.e., somatic and visceral) pain is controllable with appropriately titrated analgesic therapy. Some neuropathic pains, such as invasive and compressive neuropathies, plexopathies, and myelopathies, may be poorly responsive to conventional analgesic therapies, short of inducing a nearly comatose state. Widespread bone metastases or end-stage pathological fractures may present similar challenges. When confronted by a pain crisis, the following considerations will be helpful:

- Differentiate terminal agitation or anxiety from “physically” based pain, if possible. Terminal symptoms unresponsive to rapid upward titration of an opioid may respond to benzodiazepines (e.g., diazepam, lorazepam, midazolam).
- Make sure that drugs are getting absorbed. The only route guaranteed to be absorbed is the IV route. Although invasive routes of drug delivery are to be avoided unless necessary, if there is any question about absorption of analgesics or other necessary palliative drugs, parental access should be established.
- Preterminal pain crises that respond poorly to basic approaches to analgesic therapy merit consultation with a pain management consultant as quickly as possible. Radiotherapeutic, anesthetic, or neuroablative procedures may be indicated.

**Management of Refractory Symptoms at the End of Life**

Sedation at the end of life is an important option for patients with intractable pain and suffering. The literature describing the use of sedation at the end of life, however, is largely anecdotal.
and refers to the use of opioids, neuroleptics, benzodiazepines, and barbiturates.199–201 The anesthetic propofol is also used.202

The depth of sedation necessary to control symptoms varies greatly. Once adequate relief is obtained, the parameters for ongoing monitoring are determined by the goal of care. If the goal of care is to ensure comfort until death, the salient parameters to monitor are those pertaining to comfort of the patient, family, and staff. See Chapter 24 for additional discussion regarding palliative sedation.

Parenteral administration of ketamine is also useful for some patients with refractory pain at the end of life. Ketamine is a potent analgesic at low doses and a dissociative anesthetic at higher doses.203 Its use under conditions of terminal crescendo-type pain may not only provide greatly improved pain relief but also allow a significant decrease in the dose of concurrent analgesics and sedatives, allowing in some cases increased interactive capability. Ketamine is usually reserved for terminal situations, due to rapidly developing tolerance and psychotomimetic effects (hallucinations, dysphoria, nightmares) that may occur with higher doses and drug accumulation (Table 6–10).204,205 Long-term IV or subcutaneous use of ketamine (e.g., over 2 months) has been reported to be effective in intractable pain states not relieved by large doses of opioids and other adjuncts.205 Haloperidol can be used to treat the hallucinations, and scopolamine may be needed to reduce the excess salivation seen with this drug. Research is needed regarding the efficacy of and adverse effects associated with the use of ketamine for intractable pain.

### Pain Control in People with Addictive Disease

The numbers of patients entering palliative care with a current or past history of addictive disease are unknown, yet thought to be significant.13,206 As approximately one third of the U.S. population has used illicit drugs, it would logically follow that some of these individuals will require palliative care. In one uncontrolled survey of people with cancer or HIV, more than half of those with HIV considered themselves to be recovering addicts.207 Therefore, all clinicians must be aware of the principles and practical considerations necessary to adequately care for these individuals (see Chapter 38 for a complete discussion of care for the addicted patient at the end of life).

The underlying mechanisms of addiction are complex, including the pharmacological properties of the drug, personality and psychiatric disorders, as well as underlying genetic factors.208 Caring for these patients can be extremely challenging. Thorough assessment of the pain and their addictive disease is critical. Defensive behavior is to be expected, therefore the interview should begin with general questions about the use of caffeine and nicotine and gradually become more specific about illicit drug use.209 Patients should be informed that the information will be used to help prevent withdrawal from these drugs, as well as ensure adequate doses of medications used to relieve pain.

Patients can be categorized in the following manner: (1) individuals who used drugs or alcohol in the past but are not using them now; (2) patients in methadone maintenance programs who are not using drugs or alcohol; (3) persons in methadone maintenance programs but who continue to actively use drugs or alcohol; (4) people using drugs or alcohol occasionally, usually socially; and (5) patients who are actively abusing drugs.210,211 Treatment is different for each group.

A frequent fear expressed by professionals is that they will be ‘duped,’ or lied to, about the presence of pain. One of the limitations of pain management is that pain, and all its components, cannot be proven. Therefore, expressions of pain must be believed. As with all aspects of palliative care, an interdisciplinary team approach is indicated. This may include inviting addiction counselors to interdisciplinary team meetings. Realistic goals must be established. For example, recovery from addiction is impossible if the patient does not seek this rehabilitation. The goal in that case may be to provide a structured and safe environment for patients and their support persons. Comorbid psychiatric disorders are common, particularly depression, personality disorders, and anxiety disorders. Treatment of these underlying problems may reduce relapse or aberrant behaviors and may make pain control more effective.212

The pharmacological principles of pain management in the person with addictive disease are not unlike those in a person without this history. Nonopioids may be used, including antidepressants, anticonvulsants, and other adjuncts. However, psychoactive drugs with no analgesic effect should be avoided in the treatment of pain. Tolerance must be considered;

### Table 6–10

<table>
<thead>
<tr>
<th>Protocol for Using Ketamine to Treat a Pain Crisis</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Bolus: ketamine 0.1 mg/kg IV. Double the dose if no clinical improvement in 5 minutes. Repeat as often as indicated by the patient’s response. Follow the bolus with an infusion. Decrease opioid dose by 50%.</td>
</tr>
<tr>
<td>2. Infusion: ketamine 0.015 mg/(kg/min) IV (about 1 mg/min for a 70 kg individual). Subcutaneous infusion is possible if IV access is not attainable. In this case, use an initial IM bolus dose of 0.3–0.5 mg/kg. Decrease opioid dose by 50%.</td>
</tr>
<tr>
<td>3. It is advisable to administer a benzodiazepine (e.g., diazepam, lorazepam) concurrently to mitigate against the possibility of hallucinations or frightful dreams because moribund patients under these circumstances may not be able to communicate such experiences.</td>
</tr>
<tr>
<td>4. Observe for problematic increases in secretions; treat with glycopyrrolate, scopolamine, or atropine as needed.</td>
</tr>
</tbody>
</table>

Adapted from Reference 205.
thus, opioid doses may require more rapid titration and may be higher than for patients without previous exposure to opioids. Requests for increasing doses may be due to psychological suffering, so this possibility must also be explored.

Consistency in the treatment plan is essential. Inconsistency can increase manipulation and lead to staff frustration. Setting limits is a critical component of the care plan, and medication contracts may be indicated. In fact, one primary clinician may be designated to handle the pharmacological management of pain. Prescriptions may be written for 1-week intervals if patients cannot manage an entire month’s supply. The prescriptions may be delivered to one pharmacy to reduce the potential for altered prescriptions or prescriptions from multiple prescribers. Writing out the number for the dose and the total number of tablets will prevent alterations of the prescription (e.g., increasing the number of tablets from 10 to 100). Use long-acting opioids whenever possible, limiting the reliance upon shortacting drugs. Avoid bolus parenteral administration, although at the end of life, infusions can be effective and diversion limited by keeping no spare cassettes or bags in the home. Weekly team meetings provide a forum to establish the plan of care and discuss negative attitudes regarding the patient’s behavior. Family meetings may be indicated, particularly if they are also experiencing addictive behaviors.

Withdrawal from drugs of abuse must be prevented or minimized. These may include cocaine, benzodiazepines, and even alcohol. Alcoholism in palliative care has been underdiagnosed. Thus, a thorough assessment of recreational drug use, including alcohol, must be conducted. This provides evidence for adherence to the treatment plan. Urine toxicology studies may be necessary. An excellent monograph detailing the clinical use of urine toxicology can be found at www.familydocs.org. Another resource is the Fast Fact Urine Drug Testing for Opioids and Marijuana available at http://www.eperc.mcw.edu.

Patients in recovery may be extremely reluctant to consider opioid therapy. Patients may need reassurance that opioids can be taken for medical indications, such as cancer or other illnesses. If patients currently are treated in a methadone maintenance program, continue the methadone but add another opioid to provide pain relief. Communicate with the program to ensure the correct methadone dose. Nondrug alternatives may also be suggested. An excellent resource for information about addiction treatment is http://www.opiateaddictionrx.info.

Nursing Interventions: Outcomes and Documentation

Quality-improvement measures to relieve pain in the palliative care setting include setting outcomes, developing strategies to maintain or meet these outcomes, and then evaluating effectiveness. Some suggested goals and outcome measures that can be used in each patient’s care plan are listed in Table 6–11.

Table 6–11
Outcome Indicators for Pain Control in the Palliative Care Setting

<table>
<thead>
<tr>
<th>Category</th>
<th>Indicators</th>
</tr>
</thead>
<tbody>
<tr>
<td>Initial Evaluation</td>
<td>Pain that is not well controlled (patient self-report of 3 out of 10 or greater than the patient’s acceptable comfort level) is brought under control within 48 hours of a patient’s initial evaluation.</td>
</tr>
<tr>
<td>Ongoing Care</td>
<td>Pain that is out of control is assessed and managed with effective intervention(s) within a predetermined time frame in all patients (set an appropriate time limit).</td>
</tr>

<td>Terminal Care</td>
<td>No patient dies with pain out of control.</td>
</tr>
<tr>
<td>Adverse Effects</td>
<td>Analgesic adverse effects and side effects are prevented or effectively and quickly managed in all patients.</td>
</tr>
</tbody>
</table>

Documentation is also essential to ensure continuity of care. Recommendations for documentation in the medical record include the following:

- Initial assessment, including findings from the comprehensive pain assessment; the current pain management regimen; prior experience with pain and pain control; patient and caregiver understanding of expectations and goals of pain management; elaboration of concerns regarding opioids; and a review of systems pertinent to analgesic use, including bowels, balance, memory, function, etc.
- Interdisciplinary progress notes, including ongoing findings from recurrent pain assessment; baseline pain scores; breakthrough pain frequency and severity with associated causes and timing of episodes; effect of pain and pain treatment on function, sleep, activity, social interaction, mood, etc.; types and effects (outcomes) of intervention, including adverse effects (bowel function, sedation, nausea/vomiting assessments); documentation of specific instructions, patient/caregiver understanding, and compliance; and patient/caregiver coping.

Comprehensive strategies to improve pain outcomes in the hospice setting have included improving professional education, developing policies and procedures, enhancing pain documentation, and instituting other performance-improvement measures. These have resulted in reduction of pain-intensity scores and other changes. More research is needed in the development of quality-improvement strategies that most accurately reflect the needs of patients and families in palliative care settings.
**CASE STUDY**

**Ms. Matthews, a Patient with Pathological Fracture of the Femur**

Ms. Matthews is a 38-year-old woman who was diagnosed with a pathological fracture of the femur due to advanced breast cancer. Her husband is very supportive, although financial difficulties require that he work two jobs. She has two school-aged children at home. The Palliative Care Consult Service (including a nurse and a physician) was asked to see her on the inpatient oncology unit to assist in pain management, because she could not tolerate lying flat to receive radiotherapy treatments. A thorough pain assessment revealed minimal to moderate (3–5/0–10 intensity scale) pain in the right femur at rest, with severe (10+) sharp, shooting pain when lying flat or weight bearing. She denied other sites of pain. Oral hydrocodone 5 mg in admixture with 500 mg of acetaminophen was given up to 8 doses per day with minimal relief. Other symptoms included difficulty sleeping due to the pain, with frequent waking through the night, and constipation (her last bowel movement was 4 days ago and her normal pattern was daily defecation). She admitted to feeling sad that she could not see her children and worried that they were not coping well with her illness. Her goals of care were to return home with good pain control.

After assessing Ms. Matthews and discussing her case with the medical and radiation oncologist, plus the advanced practice nurse who had been seeing her in the outpatient clinic, her analgesic regimen was changed to include long-acting oxycodone 20 mg every 12 hours, supplemented with oral short-acting oxycodone 5 mg for breakthrough pain every hour as needed. An additional dose of short-acting oxycodone was ordered to be given 1 hour before radiotherapy treatments. Daily oral dexamethasone 12 mg also was added, along with omeprazole for GI protection. A stimulant laxative and softener were ordered to regulate the bowels.

The team reassessed Ms. Matthews’ pain during the next few days and titrated the opioids to achieve improved relief. They requested the physical therapy department to assist with teaching her family about transferring and occupational therapy to provide information regarding assistive devices. The expressive arts therapist was consulted to explore Ms. Matthews’ sadness, and to work with her children during their visits. The social worker was contacted to discuss equipment that might be needed in the home, safety issues, and support that might be offered to address financial concerns. She also offered to contact the children’s school to alert the teachers regarding their mother’s illness as a source of stress for the children, yet Ms. Matthews declined this suggestion. The chaplain was asked to see Ms. Matthews to address potential spiritual issues. A family meeting was called to discuss goals of care and preparation for home. Ms. Matthews returned home safely and with good pain relief, with ongoing follow-up from the palliative care clinic.

**Conclusion**

Pain control in the palliative care setting is feasible in the majority of patients. For patients whose pain cannot be controlled, sedation is always an option. Understanding the barriers that limit relief will lead to improved education and other strategies to address these obstacles. Developing comfort and skill with the use of pharmacological and nonpharmacological therapies will enhance pain relief. Quality improvement efforts within a palliative care setting can improve the level of pain management within that organization and ultimately the pain relief experienced by these patients. Together, these efforts will reduce suffering, relieve pain, and enhance the quality of life of those at the end of life.

**REFERENCES**

Fatigue

The deadening fatigue which invades the very bones of cancer patients is totally unlike even the most profound fatigue experienced by a well person.—M.J. Poulson

Patients do not have the energy, words, or language that would make doctors, nurses, and other health care professionals understand just how tired they feel.1 Fatigue is a devastating symptom that deserves the same attention that pain and other well-recognized symptoms of chronic illness receive. Fatigue is the symptom that has the greatest potential for hindering the optimism of patients that they will one day be well again.1

Definitions of Fatigue

I sit down in a chair and cannot will myself to get up . . . I tell my husband, “If you want to eat dinner, then you’ll have to get it for us, I’m not doing it.” He tells me how this has happened to “both of us,” but I only see that I’m the one who cannot function the way that I used to.—A patient

Fatigue is an example of a complex phenomenon that has been studied by many disciplines but has no widely accepted definition.7 The discipline of nursing is no exception. Even within different specialties of nursing, there has been little agreement on a definition of fatigue. In oncology, for example, patients perceive fatigue differently depending on where in the disease trajectory fatigue occurs. Fatigue is often the symptom that causes the patient with an undiagnosed cancer to seek medical treatment. Once diagnosed, the cancer patient experiences fatigue as a side effect of treatment. The patient who has finished treatment and is in recovery discovers a “new normal” level of energy. The patient who has experienced a recurrence of cancer considers fatigue to be as much an enemy as the diagnosis itself. Finally, the patient who is in the advanced stages of cancer interprets fatigue as the end of a very long struggle to be endured. It is not surprising then that a unifying definition has not been adopted.

The National Comprehensive Cancer Network (NCCN) Fatigue Practice Guidelines Panel, charged with synthesizing
research on fatigue to develop recommendations for care, defines fatigue as “an unusual, persistent, subjective sense of tiredness related to cancer or cancer treatment that interferes with usual functioning.”

This definition is similar to that of a multiple sclerosis panel that defined fatigue as a subjective lack of physical and/or mental energy perceived by individuals that interferes with usual and desired activities. While other definitions have been proposed, two key elements in most definitions appear to be the subjective perception as well as interference with functioning.

As with adults, no universal definition for fatigue in children has been agreed upon, but two definitions were identified. Fatigue derived from a group of 7- to 12-year-old pediatric oncology patients consisted of “a profound sense of being weak or tired, or of having difficulty with movement such as using arms or legs, or opening eyes.” In the same study, 13- to 18-year-old pediatric oncology patients’ fatigue was described as “a complex, changing state of exhaustion that at times seems to be a physical condition, at other times a mental state, and still other times to be a combination of physical and mental tiredness.” The children’s definition emphasizes a physical sensation (weakness), whereas the adolescents’ definition accentuated both physical and mental exhaustion. These researchers concluded that fatigue existed within the greater context of the child’s developmental stage and that the developmental stage might have a greater impact when evaluating fatigue than has yet been appreciated.

More recently, researchers identified three different types of fatigue in a study of pediatric oncology patients, 5 to 15 years of age: typical tiredness (normal ebb and flow of energy), treatment fatigue (energy loss greater than replenishment), and shutdown fatigue (profound, sustained loss of energy). Additional exploratory research is needed to confirm the findings of these pioneers in pediatric cancer fatigue.

Prevalence

During my radiation treatment I remember sitting in my car in the cancer center parking lot without moving for quite some time. I remember the social worker tapping on the window and asking me if I needed help. I could only say, “Please call my son to pick me up, I don’t have the energy to put the car in gear.”—A patient

Research in the palliative care arena has focused primarily on adults.\textsuperscript{11–33} One prospective study of fatigue compared advanced cancer patients to age- and sex-matched controls. The control group had a moderate excess of women (57%), with 49% (48/98) who were overweight and 50% having at least one concomitant medical problem, such as arthritis, airflow limitation, or hypertension.\textsuperscript{12} Although both patients and controls complained of a degree of fatigue, the severity of symptoms in patients was much worse. The prevalence of severe subjective fatigue (defined as a score on the fatigue scale of greater than the 95th percentile of controls) was 75% in the advanced cancer group. In this patient group, there were a variety of cancer diagnoses (breast, lung, and prostate) and many of the patients were also taking opioid medications.\textsuperscript{12}

Another relevant study, conducted by the World Health Organization, included 1840 palliative care patients.\textsuperscript{14} The prevalence of nine symptoms (pain, nausea, dyspnea, constipation, anorexia, weakness, confusion, insomnia, and weight loss) was examined in seven palliative care centers from the United States, Europe, and Australia. With the exception of moderate to severe pain, weakness was the most common symptom, reported by 51% of patients.\textsuperscript{14}

Cancer is only one of many diseases in which fatigue is a common symptom. Table 7–1 presents prevalence rates for a variety of common chronic illnesses. Of note, 11% to 25% of patients present with chronic fatigue as their chief complaint in primary care settings.\textsuperscript{15} Of these, 20% to 45% will have a primary organic cause and 40% to 45% will have a primary psychiatric disorder diagnosed. The remaining patients will either meet the CDC criteria for CFS or remain undiagnosed.\textsuperscript{15}

The amount of research conducted on the symptom of fatigue has been increasing steadily over the past 2 decades.\textsuperscript{16} However, the majority of this research has been conducted on adults. Fatigue research in children and adolescents has received little attention.\textsuperscript{17} The prevalence of fatigue in children is difficult to gauge from the general lack of research, but one study in 75 school-aged children receiving cancer treatments reported a prevalence rate of 50%.\textsuperscript{18} Fatigue was expressed by the children as being tired, not sleeping well, and not being able to do the things they wanted to do. More than half the children were not as active as before the illness and reported playing less. No studies on fatigue in children with advanced cancer were identified.

Pathophysiology

I had a dream that my sister wanted me to take a walk with her. In the dream, I remember clearly that I told her that we would have to walk another time as I was too tired to go with her. It is really strange, that even in my dreams, I’m fatigued.—A patient

Models to explain the causes of fatigue have been developed by different disciplines in the basic sciences and by clinicians. Table 7–2 represents a variety of theories, models, or frameworks to explain cancer-related fatigue that have been reported in the literature. The two most prominent theories are presented in more detail below. While these models were developed with the cancer patient in mind, the depletion model may also be applied to end-stage renal disease and the central peripheral model may be applied to multiple sclerosis.

Anemia, a deficiency of red blood cells or lack of hemoglobin that leads to a reduction in oxygen-carrying capacity of the blood, is an example of the depletion theory. Anemia is a common occurrence in patients with advanced disease or those receiving aggressive therapy.\textsuperscript{19} Multiple studies evaluating recombinant erythropoietin in patients with end-stage renal failure, orthopedic surgery, and those receiving chemotherapy for cancer have demonstrated an improvement in fatigue, exercise capacity, muscle strength, and performance of daily activities.\textsuperscript{20} Although there is reliable evidence that fatigue can be caused by anemia,\textsuperscript{21} little is known about the relationship between the degree or rate of hemoglobin loss and the development of fatigue. One study described results of a new questionnaire that was tested on a sample of 50 patients with either solid tumors or hematological malignancies.\textsuperscript{22} The fatigue subscale, a new addition to the Functional Assessment of Chronic Illness Therapy Measurement System, was able to distinguish patients with a hemoglobin level greater than 12 g/dL from those with a level less than 12 g/dL. Research on patients with end-stage renal disease indicates no relationship between hematocrit and subjective fatigue, even though anemia is a major side effect of the disease.\textsuperscript{23,24} While one study demonstrated some association between subjective fatigue and anemia, it is by no means conclusive and suggests that further research is needed.\textsuperscript{24}

Recent studies have linked inflammatory processes to central nervous system-mediated fatigue.\textsuperscript{25–27} Proinflammatory cytokines may be released as part of the host response to the tumor or in response to tissue damage (from injury) or depletion of immune cells associated with cancer treatments.\textsuperscript{28} These inflammatory stimuli can signal the central nervous system (CNS) to generate fatigue, as well as changes in sleep, appetite reproduction and social behavior.\textsuperscript{27}

The search for foundational causes of fatigue continues because no one theory thoroughly explains the basis for fatigue in the patient with advanced disease. The search for such a theory is complicated. Fatigue, like pain, is not only explained by physiological mechanisms, but must be understood as
<table>
<thead>
<tr>

a multicausal, multidimensional phenomenon that includes physical, psychological, social, and spiritual aspects. As such, factors influencing fatigue are beginning to be addressed.

**Factors Influencing Fatigue**

*Keep talking to me and hold my hand… I know you’re there and I want to open my eyes and talk with you, but I just don’t have the energy to keep my eyelids open.—A patient*

Characteristics that may predispose patients with advanced disease to develop fatigue have not been comprehensively studied. Oncology research has placed importance on patient characteristics in treatment-related fatigue. Table 7–3 provides a list of factors that have been associated with cancer-related fatigue. Several of these factors have been studied and are presented in some detail below.

Age is one factor that has been examined in several studies of treatment-related fatigue in oncology. The majority of completed research indicates that younger adult patients with cancer report more fatigue than older patients with cancer.22,24 This suggests that reported fatigue may be influenced by the developmental level of the adult. For example, young adults may have heavy responsibilities of balancing career, marriage, and child-rearing, while older adults may be at the end of their careers or retired with empty nests. Additionally, the older adult often has more than one medical condition and may even attribute the fatigue to advancing age, thereby not viewing it as abnormal. These may partially explain why younger adults have reported fatigue more frequently.

Psychological depression has been linked to patients with cancer-related fatigue.29–31 Depression and fatigue are two related concepts. Fatigue is part of the diagnostic criteria for depression,32 and depression may develop as a result of being fatigued.33 While depression is less frequently reported than fatigue, feelings of depression are common in patients with cancer, with a prevalence rate in the range of 20% to 25%.34,35 One study exploring correlates of fatigue found a fused relationship between depression and fatigue. This research indicated that fatigued women scored twice as high on the depression scale as those who were not fatigued and also that depression was the strongest predictor of fatigue.36 Additionally, depression and fatigue may coexist with cancer without having a causal relationship, because each can originate from the same pathology.33,37

Recent information derived from the scientific literature supports the notion that advanced stage of disease compounds the level of fatigue. Evidence demonstrates that the more advanced the cancer, the greater the occurrence of subjective fatigue.38 Fobair and colleagues39 interviewed 403 long-term survivors of Hodgkin’s lymphoma who had completed their initial therapy between 1 and 21 years before. Patients were asked if their energy had changed, and, if it had changed, how long it took to return to normal. Patients whose energy level had not returned to normal were more frequently found to be in the later stages of the disease. Additional research by Wang and colleagues39 that examined fatigue severity and fatigue interference in hematological malignancies, indicated that patients with acute leukemia reported more severe fatigue when compared with chronic leukemia or non-Hodgkin’s lymphoma. Their research also indicated that nausea was the clinical predictor of severe fatigue.

As illustrated by the following case reports, patient perceptions may be influenced by other symptoms.

### Case Study

**Mrs. Patterson, a Patient with Stage III Breast Cancer**

Mrs. Patterson is a 65-year-old retired postal inspector. She attends night school, taking economics and international business classes, plays golf a couple of times a week, and has a rigorous walking routine for exercise. She was recently diagnosed with stage III breast cancer, and had surgery and radiotherapy. She participated in a fatigue study to help identify physiological indicators of fatigue. At baseline and midradiation treatment, her fatigue intensity was “0” or no fatigue.

At the end of treatment, Mrs. Patterson rated her fatigue as an “8,” severe fatigue. She had been able to play golf 2 weeks before and had to cut her walking time from 45 minutes to 15 minutes. She was studying for a test and could not comprehend what she had read. When she sat and read, she would fall asleep. She used to watch her husband fall asleep while reading shortly before he died. He had non–small-cell lung cancer and died 2 years ago. His tendency to fall asleep like that was incomprehensible to her until now.

At 2 months’ postradiation therapy, Mrs. Patterson rated her fatigue as a “9.” She was forcing herself to attend night classes, two evenings a week from 7 to 10 PM. When not in school, she would go to bed between 8 and 9 PM and wake up in the morning between 5 and 6 AM. She was also taking 21/2-hour naps every day. She started to play golf again once a week, but was exhausted after only nine holes. She continued to walk but not as far or as long as before. She received a B on her exam (previously a straight-A student), but felt her concentration was improving.

One month later, Mrs. Patterson was contacted by phone at home. She was obviously short of breath, but remarked that she had just crawled up the side of a hill where she had been installing a sprinkler system for her flowers. On further discussion, she reported that her family and friends had been installing a sprinkler system for her flowers. On further discussion, she reported that her family and friends had been commenting on her shortness of breath for weeks. She had just crawled up the side of a hill where she had been installing a sprinkler system for her flowers. On further discussion, she reported that her family and friends had been commenting on her shortness of breath for weeks. She was also taking 21/2-hour naps every day. She started to play golf again once a week, but was exhausted after only nine holes. She continued to walk but not as far or as long as before. She received a B on her exam (previously a straight-A student), but felt her concentration was improving.

One month later, Mrs. Patterson was contacted by phone at home. She was obviously short of breath, but remarked that she had just crawled up the side of a hill where she had been installing a sprinkler system for her flowers. On further discussion, she reported that her family and friends had been commenting on her shortness of breath for weeks. She was also taking 21/2-hour naps every day. She started to play golf again once a week, but was exhausted after only nine holes. She continued to walk but not as far or as long as before. She received a B on her exam (previously a straight-A student), but felt her concentration was improving.

When considering postradiation patient assessment, this case study illustrates the importance of evaluating symptoms and obtaining analysis of the patient’s condition over time. At end of treatment, the patient indicated a fatigue level at “8.” Two months later, her self-rated fatigue advanced to a “9.” At the 3-month postradiation check, the patient experienced severe dyspnea, yet she had not deduced that this experience was other than a normal response to treatment. A thorough assessment and management of the fatigued patient is illustrated in the algorithm depicted in Figure 7–1.

The variance in fatigue level. The authors explained this variance as a result of the female patients’ higher degrees of pain and poor quality of sleep.

Various physical symptoms were also identified as affecting fatigue in a study of 80 women with congestive heart failure. Women were interviewed 12 months after hospitalization for heart failure. A second interview occurred 18 months later. Sleep difficulties, chest pain, and weakness accounted for a unique variance in fatigue during the first interview. By the second interview, dyspnea was the only symptom that explained the variance in fatigue level.

Fatigue in children and adolescents with advanced cancer has not been addressed. However, research has begun on pediatric oncology patients’ reports of factors influencing their fatigue. In one study, for example, 7- to 12-year-old patients with cancer viewed hospital noises, new routines, changing sleep patterns, getting treatment, and low blood counts as contributing factors to the development of fatigue. In the same study, 13- to 18-year-old patients reported that going for treatment, noisy nurses and inpatient children, changes in sleep position, boredom, being fearful or worried, and treatment side effects led to their fatigue. In another pediatric study on end-of-life symptoms and suffering, parents related that 89% of their children experienced substantial suffering from fatigue, pain, or dyspnea. When asked whether treatment for these symptoms was successful, parents indicated success in 27% of those with pain and only 16% of those with dyspnea.

Little research on factors influencing fatigue in patients with advanced cancer has been conducted. However, results from treatment-related fatigue research do give direction for assessment and management of fatigue in the palliative care setting.
Patients with Cancer-Related Fatigue

Evaluation of Fatigue

Assess characteristics or manifestations
- Severity
- Onset, duration, pattern and course
- Exacerbating and palliative factors
- Distress and impact
- Manifestations may include
  - Lack of energy
  - Weakness
  - Somnolence
  - Impaired thinking
  - Mood disturbance

Assess related constructs
- Overall quality of life
- Symptom distress
- Goals of care

Evaluation of Predisposing Factors and Etiologies

Physiologic
- Underlying disease
- Treatments
- Intercurrent disease processes (e.g., infection, anemia, electrolyte disturbance or other metabolic disorder, neuromuscular disorder)
- Sleep disorder
- Possible polypharmacy

Psychologic
- Mood disorder
- Stress

Management of Fatigue
- Establish reasonable expectations
- Plan to assess repeatedly

Correction of potential etiologies

Depression or Pain

Antidepressants
- Selective serotonin reuptake inhibitors
- Secondary amine tricyclics
- Bupropion

Analgesics

Anemia
 Exclude common causes of anemia.
- Iron deficiency
- Bleeding
- Hemolysis
- Nutritional deficiency
Severe anemia
- Transfuse
Mild to moderate anemia
- Consider epoetin alfa
  - 10,000 U SQ 3 times/wk.
- Evaluate after 4 weeks.
  - If increase in hemoglobin is > 1 g/dL, continue therapy.
  - If increase in hemoglobin is < 1 g/dL, increase dosage to 20,000 U 3 times weekly.
  - If no response, discontinue epoetin alfa.
- Provide supplemental iron as needed.

Sleep disorder
- Sleep hygiene
- Careful use of hypnotics

Other Conditions
- Correct fluids and electrolytes
- Replace calcium, thyroid or corticosteroids.
- Give oxygen.
- Treat infection.
- Reduce or eliminate nonessential meds.

Pharmacological Treatment
 Psychostimulants
- Methylphenidate
- Pemoline
- Dextroamphetamine
Low-dose corticosteroids
- Dexamethasone
- Prednisone

Fatigue nonresponsive to other interventions
- Empiric trial of antidepressant
  - Selective serotonin reuptake inhibitors
  - Secondary amine tricyclics
  - Bupropion
- Empiric trial of amantadine

Nonpharmacological Treatment
 Patient education
 Exercise
 Modify activity and rest patterns (sleep hygiene)
 Stress management and cognitive therapy
 Adequate hydration and nutrition

Figure 7–1. Algorithm for the evaluation and management of cancer-related fatigue. (Source: Portenoy RK, Itri LM. Cancer-related fatigue: guidelines for evaluation and management. Oncologist 1999;4:5. Copyright 1999 AlphaMed Press. Reprinted with permission.)
Assessment

They told me that I might experience fatigue. But I thought, “who cares about that, I have cancer.” Now I know what they meant. I could have never anticipated how completely consuming the fatigue would be.—A patient

Fatigue assessment of the whole person remains paramount and includes the consideration of the body as well as the mind and spirit (Figure 7–1). When assessing fatigue, one may refer to the current literature regarding pain assessment for assistance. In pain assessment, the patient is the one whose opinion is most highly regarded. Pain is whatever the patient says it is; so, too, it should be with fatigue. Caregiver or staff perceptions may be quite different from those of the person experiencing fatigue. There is no agreement as to the perfect definition for fatigue; therefore, it is most efficient to use an individual patient’s definition or description of fatigue. This personal fatigue may include any reference to or decrease in energy, weakness, or feeling tired or ‘wiped out.’

There are numerous methods of assessing fatigue. Many scales have been developed to measure fatigue in the adult, with varying levels of research-related validity and reliability. Current fatigue measurement tools include the Multidimensional Assessment of Fatigue, the Symptom Distress Scale, the Fatigue Scale, the Fatigue Observation Checklist, and a Visual Analogue Scale for Fatigue.50 These scales are available for use in research and may be used in the clinical area. One scale that has been used extensively in the oncology population is the Piper Fatigue Scale.51 This questionnaire has 22 items that measure four dimensions of fatigue: affective meaning, behavioral/severity, cognitive/mood, and sensory. This scale measures perception, performance, motivation, and change in physical and mental activities.52

In clinical practice, however, a verbal rating scale may be the most efficient. Fatigue severity may be quickly assessed using a “0” (no fatigue) to “10” (extreme fatigue) scale. As with the use of any measure, consistency over time and a specific frame of reference are needed. During each evaluation, the same instructions must be given to the patient. For example, the patient may be asked to rate the level of fatigue for the past 24 hours.

Fatigue, as with any symptom, is not static. Changes take place daily and sometimes hourly in the patient with advanced disease. As such, fatigue bears repeated evaluation on the part of the health care provider. One patient, noticing the dramatic change in his energy level, remarked ‘Have I always been this tired?’ He seemed unsure whether there had ever been a time when he did not feel overwhelmed by the impact of fatigue. The imperative for palliative care nursing is simply to ask the patient and continue to ask, while keeping in mind that the ultimate goal is the patient’s comfort. An example of a thorough assessment of the symptom of fatigue is found in Table 7–4.

Fatigue assessment tools for use in the pediatric population are in the developmental stages. Additionally, many questionnaires developed for the adult patient with cancer may provide a framework for use in pediatrics. Until then, a simple assessment of fatigue severity may be incorporated.

Management/Treatment

I fall into bed exhausted. I can’t wait one minute longer or speak one more sentence. But within a couple of hours, I’m wide awake. My eyes will not rest, my mind will not rest. It’s horrible not being able to sleep when I know I’m completely spent. What is wrong with me? I need to be knocked out so I can get some sleep.—A patient

When considering palliative care, the management of fatigue is extremely challenging. By its very definition, palliative care may encompass a prolonged period before death, when a person is still active and physically and socially participating in life, to a few weeks before death, when participatory activity may be minimal. With fatigue interventions, the wishes of the patient and family are paramount. One must consider management in the context of the extent of disease, other symptoms (pain, nausea, diarrhea, etc.), whether palliative treatment is still in process, age and developmental stage, and the emotional “place” of the patient.

Interventions for fatigue have been suggested to occur at two levels: managing symptoms that contribute to fatigue and the prevention of additional or secondary fatigue by maintaining a balance between restorative rest and restorative activity.53 Fatigue interventions have been grouped into two broad categories: medical interventions and nursing interventions.

Medical Intervention

Pharmacological approaches to treat fatigue have been sparse with regard to palliative care (Table 7–5). Categories of pharmacological therapies that have been used in limited numbers in this patient population are stimulants, antidepressants and low-dose steroids.54 Methylphenidate, a psychostimulant, has been shown to improve quality of life when given to depressed, terminally ill patients. It has also been shown to counteract opioid somnolence, enhance the effects of pain medication, improve cognition, and increase patient activity level.55,56 Appropriate dosing for this drug is between 5 mg–10 mg orally at breakfast and 5 mg at lunch daily. The elderly may require a downward dose adjustment.

Another stimulant that has been used in the past to treat fatigue is Pemoline. Liver toxicities have caused concern with this drug, and, subsequently, its use tends to be avoided. Dextroamphetamine are a potent CNS stimulant that may also be used. They are quickly absorbed from the gastrointestinal tract with high concentrations in the brain.

Antidepressants have shown effectiveness when a patient experiences both fatigue and depression. Efficacy has been shown with both nortriptyline and amitriptyline.54 Corticosteroids have been used to increase energy levels at a dose of
Fatigue

Prednisone has been shown to decrease the degree of fatigue experienced in some patients. Results from one study indicated an increase in activity level when palliative care patients were treated with methylprednisolone. The side effects that may occur with these drugs are always a concern.

Anemia as a result of chemotherapeutic regimens has been the most responsive to intervention. Erythropoietin alpha has been critical in increasing hemoglobin levels to obtain the highest quality of life possible for cancer patients. Doses vary in timing from 10,000 U subcutaneously given three times per week, to 40,000 U once a week, with a similar increase in hemoglobin level. In one study of 4382 anemic cancer patients, the highest quality of life was experienced when hemoglobin was maintained between 11 g–13 g/L with the use of epoetin alfa.

Nonpharmacological Nursing Interventions

Historically, nurse clinicians and researchers have been the trailblazers in assessing and managing fatigue in the clinical setting. Research has been conducted on all of the fatigue management strategies listed below, but sample sizes have often been small and homogeneous. Much more research is needed, but the beginning evidence is encouraging (Table 7–6).

Table 7–4
Fatigue Assessment

<table>
<thead>
<tr>
<th>Location: Where on the body is the fatigue located: Upper/lower extremities? All muscles of the body? Mental/attentional fatigue? Total body fatigue?</th>
</tr>
</thead>
<tbody>
<tr>
<td>Intensity/severity: Does the fatigue interfere with activities (work, role/responsibilities at home, social, things the patient enjoys)?</td>
</tr>
<tr>
<td>Duration: How long does the fatigue last (minutes, hours, days)? Has it become chronic (more than 6 months’ duration)? What is the pattern (wake up from a night’s sleep exhausted, evening fatigue, transient, unfading, are circadian rhythms affected)?</td>
</tr>
<tr>
<td>Aggravating factors: What makes it worse (rest, activity, other symptoms, environmental heat, noise)?</td>
</tr>
<tr>
<td>Alleviating factors: What relieves it (a good night’s rest, food, listening to music, exercise)?</td>
</tr>
<tr>
<td>Patient’s knowledge of fatigue: What meaning does the patient assign to the symptom of fatigue (getting worse, disease progression, dying)?</td>
</tr>
<tr>
<td>Medications: Is the patient taking any medications that could cause the fatigue (for pain or sleep)?</td>
</tr>
<tr>
<td>Physical exam based on subjective symptom: Is there anything obvious on exam that could account for the fatigue (nerve damage, malnourished, dehydrated)?</td>
</tr>
<tr>
<td>Muscle strength: Tests to elicit muscle strength are available (Jamar grip strength, nerve conduction studies).</td>
</tr>
<tr>
<td>General appearance: Often, there is nothing in a patient’s general appearance to indicate how fatigued he or she is; however, some patients do exhibit signs such as appearing pale or having a monotone voice, slowed speech, short of breath, obvious weight loss, dull facial expression.</td>
</tr>
<tr>
<td>Vital signs: Anything out of the ordinary to explain their fatigue (fever, low blood pressure, weak pulse)?</td>
</tr>
<tr>
<td>Laboratory results: Oxygenation status (blood gases, hemoglobin, hematocrit), electrolytes, other hormones such as thyroid?</td>
</tr>
<tr>
<td>Level of activity: Have usual activities changed?</td>
</tr>
<tr>
<td>Affect: What is the patient’s mood (anxious, depressed, flat)?</td>
</tr>
</tbody>
</table>

Several investigators have reported the benefits of a consistent exercise regime in breast cancer patients. They have found that exercise decreased perceptions of fatigue, and they indicated that those patients who exercised reported half the fatigue level of those not exercising. Whether these findings can be generalized to palliative care is unknown.

When attention-restoring interventions were used with cancer patients, it was found that attention capacity was enhanced and fatigue was reduced. These activities are based on a program that required patients to select and engage in a favorite activity for 30 minutes three times a week. The use of this technique seemed to provide restorative distraction and replace boredom and understimulation. Included in the activities were spending time in a natural environment, participating in favorite hobbies, writing, fishing, music, and gardening. Regardless of the limitations of the patients with advanced disease, incorporation of some of these activities may prove helpful.

Another broad category for fatigue intervention includes taking advantage of every educational opportunity during the advanced disease course. With education of both the patient and the family as a constant theme, every attempt should be made to forewarn of changes in disease progression, procedures, treatment, medication side effects, or scheduling. Even
a personnel change can be enough to impact the physical and emotional energy reserves. Nurse-initiated and planned educational sessions with both the patient and family give a forum in which to field forgotten questions, reinforce nutritional information, and together manage symptoms.

Sleep disruption is a common problem encountered by the patient with advanced cancer. Sleep cycles may be negatively affected by innumerable internal and external factors, whose effect should not be underestimated. Simple changes in environment and habits may improve sleep distress tremendously. One study evaluated the feasibility of sleep interventions while patients underwent adjuvant chemotherapy.65 Components of the intervention included sleep hygiene, relaxation therapy, stimulus control and sleep-restriction techniques. For those situations where pharmacological intervention is necessary, a thorough assessment of past and current sleep habits is essential. The temporary use of sleep medications such as Ambien (zolpidem tartrate) may be used to minimize sleep deprivation enough to energize the patient into trying nonpharmacological measures.

Psychosocial techniques are the last broad category of fatigue intervention. One review of 22 studies of psychosocial treatment with cancer patients reported findings that indicate that psychosocial support and individualized counseling have a fatigue-reducing effect.66 If deemed appropriate, encourage the patient and/or family to participate in disease-specific support groups, using the telephone or the Internet if unable to travel. Individual counseling by professionals in nursing, social work, or psychology are also helpful to many.

Fatigue-management interventions need to be considered within the cultural context of the patient and family. For some cultures, this may include only the “nuclear” family, whereas in other cultures, there are ritual or extended relatives. When information is shared and decisions are made regarding intervention, the “family” is acknowledged formally, and care should be made inclusive of these variations.67

Table 7–6  
Nursing Management of Cancer-Related Fatigue

<table>
<thead>
<tr>
<th>Problem</th>
<th>Intervention</th>
<th>Rationale</th>
</tr>
</thead>
</table>
| Lack of information/lack of preparation | Explain complex nature of fatigue and importance of communication with health care professionals.  
Explain causes of fatigue in advanced cancer:  
• Fatigue can increase in advanced disease.  
• Cancer cells can compete with body for essential nutrients.  
• Palliative treatments, infection, and fever increase body’s need for energy.  
• Worry or anxiety can cause fatigue as well as depression, sadness, or tension.  
• Changes in daily schedules, new routines, or interrupted sleep schedules contribute to the development of fatigue.  
Prepare patients for all planned activities of daily living (eating, moving, bath). | Preparatory sensory information reduces anxiety and fatigue.  
Realistic expectations decrease distress and decrease fatigue. |
| Disrupted rest/sleep patterns    | Establish or continue regular bedtime and awakening.  
Obtain as long sleep sequences as possible, plan uninterrupted time.  
Rest periods or naps during the day, if needed, but do not interfere with nighttime sleep.  
Use light sources to cue the body into a consistent sleep rhythm.  
Pharmacological management of insomnia should be used only when behavioral and cognitive approaches have been exhausted. | Curtailing time in bed, unless absolutely necessary, helps patient feel refreshed and avoids fragmented sleep, strengthens circadian rhythm. |
| Deficient nutritional status     | Recommend nutritious, high-protein, nutrient-dense food to make every mouthful of food “count”.  
Suggest more small, frequent meals.  
Use protein supplements to augment diet.  
Encourage adequate intake of fluids, recommend 8–10 glasses or whatever is comfortably tolerated unless medically contraindicated to maintain hydration.  
Frequent oral hygiene.  
Corticosteroids may be prescribed to assist with appetite stimulation. | Food will help energy levels; less energy is needed for digestion with small, frequent meals. |
| Symptom management               | Control contributing symptoms (pain, depression, nausea, vomiting, diarrhea, constipation, anemia, electrolyte imbalances, dyspnea, dehydration).  
Assess for anemia and evaluate for the possibility of medications or transfusion. | Managing other symptoms requires energy and may interfere with restful sleep. |
| Distraction/restoration          | Encourage activities to restore energy: spending time in the natural environment, listening to music, praying, meditating, engaging in hobbies (art, journaling, reading, writing, fishing), spending time with family and friends, joining in passive activities (riding in car, being read to, watching meal preparation). | Pleasant activities may reduce/relieve mental (attentional) fatigue. |

(continued)
Summary

This chapter has provided an overview of fatigue as it spans the illness trajectory and end-of-life experience. While fatigue is a complex phenomenon that has been widely studied, there is no universally accepted definition. Fatigue is experienced by individuals with various chronic diseases; is influenced by many factors such as age, depression, stage of disease and other concurrent symptoms; and has numerous causes. The authors have provided a fatigue-assessment checklist that can be used to identify potential sources and/or antecedents for the patient’s fatigue. Because there is no instant cure for fatigue, the patient experiencing it may be frustrated and reluctant to use the practical interventions. Nurses are challenged to provide current information about fatigue, its reversible causes, and its normal occurrence with various illnesses and to encourage patients to actively participate in fatigue-management strategies.

59. Crawford J, Cella D, Credle CS, Cremieux PY, Demetri GD, Sarokhan BJ, Slavin MB, Glaspie JA. Relationship between changes
Anorexia and Cachexia

When you can't eat, you're just no longer a part of your family. There's no need for me to go to the dinner table but sometimes I go so my family won't feel so sad. They try all the time to help me eat but I just can't. I know it adds to their suffering, I think it's worse than the pain.—A woman with lung cancer

Key Points

- Anorexia and cachexia are a distressing part of advanced illness.
- They are distinct syndromes but clinically difficult to differentiate.
- Metabolic alterations are the primary cause of anorexia/cachexia syndrome.
- Assessment and treatment of anorexia and cachexia include determining whether exogenous etiologies such as nausea and pain are involved and vigorous treatment of any such etiologies if present.

Anorexia, the “lack or loss of appetite, resulting in the inability to eat,” and resulting weight loss are common in many illnesses.1 In the early stages, anorexia usually resolves with resolution of the illness, and any weight lost may be replaced with nutritional supplements or increased intake.2–4 Unchecked, anorexia (or decreased nutritional intake from other causes such as lack of available food) leads to protein calorie malnutrition (PCM) and weight loss, primarily of fat tissue but also of lean muscle mass. These conditions are common among patients with advanced cancer and acquired immune deficiency syndrome (AIDS).3,5

Cachexia, a condition distinct from anorexia or simple starvation from decreased food intake, also is common in cancer and AIDS, as well as other advanced conditions, including congestive heart failure, severe sepsis, tuberculosis, rheumatoid arthritis, and malabsorption.6–9 The word “cachexia” is derived from the Greek kakos, meaning bad, and hexis, meaning condition. Cachexia is defined as a state of “general ill health and malnutrition, marked by weakness and emaciation”; it occurs in more than 80% of patients with cancer before death and is the main cause of death in more than 20% of such patients.4,10 In contradistinction to anorexia or starvation, in cachexia, there is approximately equal loss of fat and muscle, significant loss of bone mineral content, and no response to nutritional supplements or increased intake. Weight loss, regardless of etiology, has a decidedly negative effect on survival, and loss of lean body mass has an especially deleterious effect.4,10

In patients with cancer, weight loss is most common in cancers of digestive organs (stomach, pancreas, colon) and is also common in (but not limited to) solid tumors. However, even in digestive organ cancers, the weight loss is not due solely to decreased digestive function but also to other metabolic processes, as described below.10–13

Cachexia was previously considered to result from tumor energy demands and/or an advanced state of anorexia, but

Metabolic Alterations as the Primary Cause of Anorexia/Cachexia Syndrome

Metabolic alterations are common (and in many respects similar) in cancer and AIDS and are thought to be due in large part to the systemic inflammatory response and stimulation of cytokine production (principally tumor necrosis factor alpha [TNF-α], prostaglandins [PG], interleukin-1 [IL-1], interleukin-6 [IL-6], interferon α [IFN-α], and interferon β [IFN-β]). Other catabolic tumor-derived factors thought to play a role in cachexia include proteolysis-inducing factor (PIF) and lipid mobilizing factor (LMF). Note, however, that cachexia is incompletely understood and a clear cause-and-effect link has been established only with TNF-α, LMF, and PIF. At least initially, the metabolic alterations cause the anorexia rather than the anorexia causing the metabolic alterations. Major metabolic alterations include glucose intolerance, insulin resistance, increased lipolysis, increased skeletal muscle catabolism, negative nitrogen balance, and, in some patients, increased basal energy expenditure. Table 8–2 lists metabolic abnormalities in ACS.

Paraneoplastic Syndromes

Metabolic paraneoplastic syndromes, such as hypercalcemia or hyponatremia (syndrome of inappropriate antidiuretic hormone) may also cause anorexia or symptoms such as fatigue that contribute to anorexia. Paraneoplastic gastrointestinal tract syndromes, such as esophageal achalasia or intestinal pseudoobstruction, result in decreased intake and, thus, PCM.

Physical Symptoms

A number of physical symptoms of advanced disease may contribute to or cause anorexia, including pain, dysguesia (abnormalities in taste, especially aversion to meat), ageusia (loss of taste), hyperosmoria (increased sensitivity to odor), hyposmia (decreased sensitivity to odor), anosmia (absence of sense of smell), stomatitis, dysphagia, odynophagia, dyspnea, hepato-megaly, splenomegaly, gastric compression, delayed emptying, malabsorption, intestinal obstruction, nausea, vomiting, diarrhea, constipation, inanition, asthenia, various infections (see below), and early satiety. Alcoholism or other substance dependence may also contribute to or cause anorexia. Primary or metastatic disease sites have an effect on appetite, with cancers, such as gastric and pancreatic, having direct effects on organs of alimentation.

Each of these should be ruled out as a primary or contributing cause of anorexia and, if present, treated as discussed elsewhere in this book. In general, people who are seriously ill and/or suffering distressing symptoms have poor appetites. Many cancer or human immunodeficiency virus (HIV) treatments have deleterious effects on appetite or result in side effects leading to anorexia and/or weight loss (see

Etiologies and Process

Common causes of anorexia and/or ACS are described below. Anorexia or ACS may be considered primary if resulting from endogenous metabolic abnormalities such as cytokine production stimulation and secondary if resulting from symptoms or exogenous etiologies such as pain, depression, nausea, or obstruction.
Medication Side Effects, below). Patients with HIV disease may also develop primary muscle disease, leading to weight loss.

**Medication Side Effects**

Side effects of medications (especially those used to treat HIV infection, such as acyclovir, ethambutol, foscarne, ganciclovir, isoniazid, interferon, pyrimethamine, zidovudine, and others) may directly result in anorexia or have side effects such as nausea, taste changes, and diarrhea that lead to anorexia and PCM. While aggressive curative treatment is seldom appropriate for patients with terminal illness, it is not always possible to discern who is terminal, who is not terminal, and, if terminal, how much time remains. Moreover, palliative care is not restricted to patients who are expected to die. Cytotoxic drugs that tend to be most emetic are cisplatin, dacarbazine, cyclophosphamide, carboplatin, and streptozocin. Moderate emetic effects occur after the administration of adriamycin, methotrexate, and cytarabine.\(^{16}\)

**Psychological and/or Spiritual Distress**

Psychological and/or spiritual distress is an often overlooked cause of anorexia. The physical effects of the illness and/or treatment coupled with psychological responses (especially anxiety and/or depression) and/or spiritual distress, such as feelings of hopelessness, may result in little enthusiasm or energy for preparing or eating food. As weight is lost, changes in body image occur, and as energy decreases, changes in self image occur. Moreover, appetite and the ability to eat are key determinants of physical and psychological quality of life.\(^{15}\) In some cultures, for example, Southeast and East Asian, some degree of obesity is perceived as a sign of good health and weight loss is seen as a clear sign of declining health.\(^{17}\) For many patients, the net result of ACS and the resulting weight loss constitute a negative-feedback loop of ever-increasing magnitude and increased suffering in multiple dimensions. Clinicians evaluating patients with anorexia are encouraged to review basic principles for the assessment and management of depression as covered in

detail in Chapter 19. Treatment of underlying depression can improve appetite considerably.

**Other Physical Changes**

The fit of dentures may change with illness, or already poorly fitting dentures may not be as well tolerated in advanced disease. Dental pain may be overlooked in the context of terminal illness. Oral (and sometimes esophageal) infections and complications increase with disease progression and immunocompromise. Aphthous ulcers, mucositis, candidiasis, aspergillosis, herpes simplex, and bacterial infections cause oral or esophageal pain and, thus, anorexia.\(^{15,16}\)

**Assessment**

Assessment parameters in anorexia and ACS are summarized in Table 8–3.

Anorexia and weight loss may begin insidiously with slightly decreased appetite and slight weight loss characteristic of virtually any illness. As the disease progresses and comorbid conditions increase in number and severity, anorexia and PCM increase and a mutually reinforcing process may emerge. For example, along with the metabolic abnormalities of ACS, fatigue leads to more pronounced anorexia and PCM, which, in turn, leads to increased fatigue and weakness that may accelerate the metabolic processes of ACS.

With ACS common, and in many cases inevitable among patients with terminal illness, identifying specific causes is an extremely challenging and, in far advanced disease, an ultimately futile task. Moreover, there are no clear and widely accepted diagnostic criteria for ACS. Nevertheless, anorexia from some etiologies is treatable; hence, assessment of the possible presence of etiologies noted above is integral to quality palliative care. Other assessment parameters are used according to the patient’s ability to tolerate and benefit from the assessment. At some point in the illness, even basic assessments, such as weight, serve only to decrease the patient’s quality of life. Assessment parameters of nutritional status include decreased intake, decreased weight, muscle wasting, decreased fat, loss of strength, and changes in laboratory values. The patient is likely to report anorexia and/or early satiety and to experience a decline in mental acuity.

The following laboratory values are of significance in ACS:\(^{15}\):

- Serum albumin is influenced by a number of stressors, such as infection, hydration, and kidney or liver disease, and hence is not an accurate measure of nutritional status. Decreased serum albumin is prognostic of increased morbidity and/or mortality.
- Serum thyroxin-binding prealbumin (transthyretin) levels are indicative of visceral protein stores and nutritional status. Decreased levels indicate under-nutrition.
- Changes in other laboratory values, such as electrolyte and mineral levels, may also show changes in nutritional status.

Assessment also includes determining usual intake patterns, food likes and dislikes, and the meaning of food or eating to the patient and family. Too often, a family member attaches huge significance to nutritional intake and exerts

Anorexia and Cachexia

Interventions

There are few credible reports of nutritional interventions that reverse ACS in advanced disease. Nevertheless, the process may be slowed to some extent in early and even late disease stages, especially with the use of multimodal approaches (nutritional, combined drug therapy, exercise, psychological/social, and spiritual). There are, of course, interventions that are efficacious in treating anorexia from exogenous etiologies such as nausea or esophageal stricture. Interventions are divided into exogenous symptom management, nutritional support, enteral and parenteral nutrition, pharmacological management, and multimodal approaches.

(Exogenous) Symptom Management

The presence or absence of symptoms that may cause or contribute to anorexia and weight loss should be evaluated. If anorexia is due to an identifiable problem or problems, such as pain, nausea, fatigue, depression, or taste disorder, for example, then intervene as discussed elsewhere in this book.

Nutritional Support

Nutritional support, especially oral, to increase intake overall or to maximize nutritional content may be helpful to some extent, especially early in the disease process. As noted earlier, some degree of obesity is thought by some cultures to be a sign of good health and any weight loss to be a sign of ill health. Helping family members understand nutritional needs and limitations in terminal situations is essential. General guidelines for altering diet include the following:

- Various nutrients (fish oil, glutamine, arginine, and RNA are sometimes added)
- Fat from triglycerides or vegetable oils
- Protein from casein or whey

The nutritional quality of intake should be evaluated and, if possible and appropriate, modified to improve the quality. Patients who are not moribund may benefit from supplementary sources of protein and calories, though “taste fatigue” may result from too frequent intake of these. See “Multimodal Approach” later in this chapter.

Determine the meaning to the patient and family of giving, taking, and refusing food. In families in which dying is experienced to some extent as a time of personal growth or closeness, redirection of food-related personal values from symbolic nurturing to actual sharing is possible. Thus, even half a bite of food shared in “sacred meals” eaten with loved ones is a kind of victory over the disease or hopelessness. Usually, however, strong and even unconscious beliefs about food are difficult to modify, and many families require education and frequent support in the face of helplessness and frustration related to ever-diminishing intake.

Culturally appropriate or favored foods should be encouraged. In some cases, certain traditional foods may be thought especially nutritious and some foods with good nutritional content, harmful. Some commercial supplements (called “milk”), for example, are thought by many Southeast Asians to have highly desirable, almost magical healing properties.

Small meals, on the patient’s schedule and according to the taste and whims of the patient, are helpful, at least emotionally, and should be instituted early in the illness so that eating does not become burdensome.

Foods with different tastes, textures, temperatures, seasonings, degrees of spiciness, degrees of moisture, and colors, for example, should be tried, but the family should be cautioned against overwhelming the patient with a constant parade of foods to try. Room temperature and less spicy foods are preferred by many patients.

Different liquids should also be tried. Cold, clear liquids are usually well tolerated and enjoyed, though cultural constraints may exist. For example, patients with illnesses that are classified as “cold” by some Southeast Asians and Latinos are thought to be harmed by taking drinks or foods that are either cold in temperature or thought to have “cold” properties.

Measures as basic as timing intake may also be instituted. Patients who experience early satiety, for example, should take the most nutritious part of the meal first (usually without fluids other than nutritional supplements).

Oral care may be considered an integral part of nutritional support. Hygiene and management of any oral pain are essential in nutritional support. Procedures, treatments, psychological upsets (negative or positive), or other stresses or activities should be limited prior to meals.

Enteral and Parenteral Nutrition

Enteral feeding (via nasoenteral tube, gastrostomy, jejunostomy) is indicated in a few terminally ill patients, including those with weight loss due to, or exacerbated by, fistulas, mechanical bowel obstruction, dysphagia, odynophagia, vomiting, or malabsorption due to tumor or treatment. For short-term feeding (<4 weeks), nasoenteral feeding is commonly used, while for long-term enteral feeding (>4 weeks), gastrostomy or jejunostomy is the preferred means. A wide variety of feeding formulas exist, with many providing complete nutrition. The primary sources of nutrients are usually as follows:

- Calories from carbohydrates
- Protein from casein or whey
- Fat from triglycerides or vegetable oils
- Various nutrients (fish oil, glutamine, arginine, and RNA are sometimes added)
Specific formulas are based on various body functions (usually decreased), for instance, heart, liver, kidneys, as well as other factors.

Total parenteral nutrition (TPN) clearly has a place early in the process of cancer, for example, during some treatment regimes such as bone marrow transplantation and under circumstances noted above (dysphagia, etc.). It has greater potential for complications than does enteral nutrition, seldom improves outcome, and thus is very seldom indicated in terminally ill patients with advanced disease.4

Pharmacological Interventions

Pharmacological options to address ACS in the palliative setting are useful in early stages of illness, but futile in the final stages of terminal illness. Pharmacological options with indications and notable side effects are presented in Table 8–4.

Medications under investigation for the treatment of ACS10 include:

• Nonsteroidal antiinflammatory drugs (NSAIDs), especially cyclooxygenase-2 (COX-2) inhibitors such as celecoxib, but also COX-1 inhibitors such as ibuprofen affect the systemic inflammatory response inherent in ACS. COX-2 inhibitors also block angiogenesis and suppress tumor growth.
• Melatonin may decrease circulating levels of TNF-α.
• N-3 polyunsaturated fatty acids (PUFA) such as found in fish oil decrease TNF-α, IL-1, IL-6, and IFN-β.
• β2-adrenergic agonists (clenbuterol, salbutamol, salmeterol) given in low doses improve muscle mass status.
• Thalidomide inhibits TNF-α production and neoangiogenesis.
• Anabolic agents such as growth hormone (GH), insulin-like growth factor (IGF-1), testosterone, dihydrotestosterone, and testosterone analogs may maintain or improve lean body mass through enhanced protein synthesis.
• Anabolic androgens (synthetic derivatives of testosterone) also improve body weight, muscle mass, and performance status in wasting diseases.
• Branched-chain amino acids (BCAAs) such as leucine, isoleucine, and valine improve protein and albumin synthesis.

Medications that have not shown efficacy in the treatment of ACS include cyproheptadine, pentoxifylline, and hydrazine sulfate.21

Multimodal Approach

The devastating consequences, complexities, and resistance to the treatment of ACS lead inevitably to consideration of a multimodal approach.5,10,15,22 Such an approach could include some or all of the following:

• Prevention or early recognition and treatment of exogenous symptoms that may contribute to anorexia

Recognition and early intervention in the nutritional needs of patients with potentially life-threatening illnesses or illnesses associated with ACS

Pharmacological therapy that combines oral progesterone (medroxyprogesterone 500 mg/24 hours) with the following (note that this approach is under investigation):

- A diet high in polyphenol content (green tea, red wine, apples, oranges, onions) or supplements to increase antioxidant activity
- Oral pharmacointestinal support high in N-3 PUFA
- Antioxidant treatment with alpha lipoic acid, carbocysteine lysine salt, vitamin E, vitamin A, and vitamin C
- Celecoxib 200 mg daily
- With or without antiTNF-α monoclonal antibody (mAb)
- Resistance training to increase lean muscle mass is effective at least early in the disease process.

Clearly, the involvement of several disciplines (medicine, nursing, nutrition, physical therapy, and perhaps others) is required in this approach. The following case study illustrates some of the issues commonly associated with ACS.

**CASE STUDY**

A 58-Year-Old Woman with ACS and Alcohol Addiction

A 58-year-old woman with a diagnosis of advanced cervical carcinoma was cared for at home by family and the services of a home care agency. Despite careful symptom management and nutritional support, she continued to lose weight and suffer from increasing weakness and fatigue. She had refused several opportunities for inpatient treatment, but when she developed fever, diarrhea, and dehydration, she agreed to go to the hospital.

Within several hours of admission, she became agitated and disoriented. Her condition deteriorated rapidly; she developed chest pain and became extremely fearful and paranoid, and she began hallucinating. She was started on intravenous haloperidol with little effect. A consulting psychiatrist, called from the emergency department, determined that she was experiencing acute alcohol withdrawal. Although the patient and family had previously denied alcohol use, when confronted with her deteriorating condition, the family admitted that the patient was a heavy drinker.

She was switched to intravenous diazepam and within several days was lucid. She also was septic, requiring hospitalization for 6 weeks for treatment of her sepsis and nutritional status. In the 3rd week, she began to gain weight. She continued to gain weight throughout the hospitalization and experienced a slight increase in strength. Within a few weeks of discharge, she, unfortunately, began losing weight, and it was clear that she was again drinking. She died in an emaciated state at home several months later.

**Summary**

Increasingly, ACS is recognized as a serious aspect of advanced or terminal illness and as an area requiring further research, especially with respect to (1) the pathophysiology of cachexia and (2) increasing treatment options. Current understanding of ACS includes the following:

- Anorexia and cachexia are distinct syndromes but clinically are difficult to differentiate.
- Anorexia is characterized by decreased appetite that may result from a variety of causes (including unmanaged symptoms such as nausea and pain), it results primarily in loss of fat tissue, and resultant weight loss is reversible.
- Cachexia is a complex metabolic syndrome thought to result from the production of proinflammatory cytokines such as TNF and IL-1. In cachexia, there is approximately equal loss of fat and muscle and significant loss of bone mineral content. Weight loss from cachexia does not respond to nutritional interventions.
- Assessment and treatment of ACS include determination of whether exogenous etiologies such as nausea or pain are involved, the vigorous treatment of any such etiologies, and nutritional support if indicated.
- Treatment of cachexia is unsatisfactory, but some temporary gains may occur with progestational agents, especially megestrol acetate and a multimodal approach such as discussed above. Other pharmacological measures are also helpful.

Progress is being made in understanding and treating the problem, but ACS is neither yet completely understood nor is treatment optimized.

Nausea and Vomiting

Nausea and vomiting are symptoms commonly experienced by patients with advanced disease. Currently, the majority of available research about nausea and vomiting deals with cancer patients. Thus, this chapter will use advanced cancer patients as a model for assessment and treatment of nausea and vomiting, but these principles can also be applied to other patients with advanced disease. For cancer patients, these symptoms may be experienced secondary to the underlying malignancy as well as to the frequent side effects of the medications used to treat the cancer. To date, most research has focused on treatment-induced nausea and vomiting in patients receiving chemotherapy for cure or control of disease. Unfortunately, there is a paucity of literature about nausea and vomiting in cancer patients who are not receiving chemotherapy or who are in the terminal phase of their illness.1

Nausea and vomiting are frequent and distressing symptoms experienced by patients with advanced cancer who are receiving palliative care. Research has shown that 40% to 60% of patients with advanced cancer experience nausea and/or vomiting. Additionally, research has shown that these symptoms are more common in patients under 65 years old, in women, and in patients with cancer of the stomach or breast. For stomach cancer, the high frequency may be due to local causes such as obstruction. For breast cancer, the causes may be multifactorial and include hypercalcemia, brain metastases, medications, and gender.2-4

Ross and Alexander4 describe the 11 Ms of nausea and vomiting in terminally ill patients. These include: (1) metastases (cerebral or liver), (2) meningeal irritation, (3) movement (causing vestibular stimulation), (4) mentation (e.g., cerebral cortex), (5) medications (e.g., opioids, chemotherapy), (6) mucosal irritation (e.g., hyperacidity, gastroesophageal reflux), (7) mechanical obstruction (e.g., constipation, obstipation, tumor), (8) motility (e.g., ileus), (9) metabolic imbalance (e.g., hypercalcemia, hyponatremia), (10) microbes (e.g., esophagitis), and (11) myocardial dysfunction (e.g., ischemia, congestive heart failure). Sadly, this symptom complex of nausea and vomiting in advanced cancer has not been reduced in the past decade.

---

Cynthia King

Nausea and Vomiting

Queasiness and heaving have been my worst symptoms these last few weeks. These feelings are relentless. I am scared to eat or drink anything, but I long to taste some of my favorite foods and drink lemonade before I die. I just pray every day that I can get comfortable before I die.
—C. B., a patient 3 weeks before dying
The level of distress and sense of treatment burden associated with nausea and vomiting may be profound. If these symptoms are left untreated, they can interfere with usual daily activities, increase anxiety and other symptoms, and impair quality of life (QOL). It is essential that these symptoms be adequately treated throughout the trajectory of cancer care and across all settings. As more palliative care is provided in outpatient settings, homes, and hospices, it is important to involve the patient and family in the management of nausea and vomiting. Nurses who provide palliative care to cancer patients of any age and in any setting need to adequately assess for nausea and vomiting, provide appropriate drug and nondrug interventions, provide essential teaching of self-care to patients and families, and evaluate all interventions and self-care. The approach must be practical, with the goal being relief of symptoms as soon as possible. The treatment may be directed at the cause, at the symptom, or at both. This disruption in QOL can be of particular significance to patients facing the end of life.

Nausea and Vomiting and Quality Of Life

The distress and disruption in daily activities caused by nausea and vomiting can impair QOL for patients with advanced disease. Although there is controversy over the number and exact dimensions of QOL, the City of Hope National Medical Center QOL model includes the four dimensions of physical well-being, psychological well-being, social well-being, and spiritual well-being. The distress caused by nausea and vomiting can affect one or all of the four dimensions of QOL (Figure 9–1). Adequate management of nausea and vomiting can positively affect all dimensions of a patient’s QOL. The control of nausea and vomiting can provide patients with a sense of control over their body and life; decrease anxiety and fear; decrease caregiver burden; decrease fatigue, anorexia, and insomnia; increase physical, social, and cognitive functioning; and allow patients to carry out some of their usual daily activities.

Conceptual Concerns Related to Nausea and Vomiting

To thoroughly examine the problem of nausea and vomiting in palliative care, it is important to be clear about certain concepts. Symptoms such as nausea and vomiting are composed of subjective components and dimensions unique to each patient. Symptoms are different from signs, which are objective and can be observed by the health care professional. Symptom occurrence is comprised of the frequency, duration, and severity with which the symptom presents. Symptom distress involves the degree or amount of physical and mental or emotional upset and suffering experienced by an individual. This is different from symptom occurrence. Lastly, symptom experience involves the individual’s perception and response to the occurrence and distress of the symptom.

The terms “nausea” and “vomiting” represent clearly distinct concepts. Unfortunately, terms used to describe them are frequently used interchangeably. This may result in confusion during assessment, measurement, treatment, or patient and family education. Nausea is a subjective symptom involving an unpleasant sensation experienced in the back of the throat and the epigastrium, which may or may not result in vomiting. Other terms used by patients include “sick at my stomach,” “butterflies,” and “fish at sea.” The symptoms of increased salivation, dizziness, light-headedness, difficulty swallowing, and tachycardia may accompany the feeling of nausea. Patterns of nausea include acute, delayed, and anticipatory. Acute nausea occurs within minutes or hours after such events as having chemotherapy. Delayed nausea generally occurs at least 24 hours after events like chemotherapy and may last for several days. Anticipatory nausea occurs before the actual stimulus and develops only after an individual has had a previous bad experience with an event such as chemotherapy that resulted in nausea or vomiting.

Vomiting is often confused with nausea but is, in fact, a separate phenomenon and may or may not occur in conjunction with nausea. It is a self-protective mechanism by which the body attempts to expel toxic substances and involves the expulsion of gastric contents through the mouth, caused by forceful contraction of the abdominal muscles. Vomiting is frequently described as “throwing up,” “pitching,” “barfing,” or “upchucking.” Retching involves the spasmodic contractions of the diaphragm and abdominal muscles.
Physiological Mechanisms of Nausea and Vomiting

After thoroughly understanding the concepts of nausea and vomiting, it is important to understand the physiological mechanisms and causes of this symptom complex. Vomiting is controlled by stimulation of the vomiting center (VC) or emetic center, which is an area of the brainstem. There are multiple central and peripheral pathways that can stimulate the VC. It is important for nurses to understand these pathways to determine a cause and to select appropriate treatments. The various pathways include the peripheral pathways of the vagal afferents, the pharyngeal afferents, and the vestibular system. The central pathways include the midbrain afferents and the chemoreceptor trigger zone (CTZ) (Figure 9–2).14,16,18–20

The vagal afferent pathway involves fibers located in the wall of the stomach and proximal small intestine, which sense mechanical or chemical changes in the upper gastrointestinal tract. The pharyngeal afferent pathway involves mechanical irritation of the glossopharyngeal nerve. Excessive coughing may irritate this. The vestibular system involves stimulation starting in the inner ear. This involves nausea and vomiting resulting from such causes as motion sickness. If a patient has a prior history of motion sickness, he or she may have an increased incidence of nausea and vomiting with treatments such as chemotherapy.16,18,19

The central pathways include the midbrain and the CTZ. Intracranial pressure, stress, anxiety, sights, sounds, or tastes may stimulate the midbrain afferent pathway. The CTZ is located at the area postrema of the fourth ventricle of the brain. Once the CTZ is exposed to various neurotransmitters, such as serotonin, dopamine, histamine, or prostaglandins, nausea and vomiting may result. The vagal afferents also enter the CTZ.16–20

In the past, it was hypothesized that chemotherapy-induced nausea and vomiting occurred as a result of stimulation of the CTZ by the chemotherapy or other drugs. Although it is now known that exposure of the CTZ to the neurotransmitters is the most important factor, there is more emphasis being placed on understanding other mechanisms, such as the 5-hydroxytryptamine (5-HT) receptor sites in the small intestine. In newer theories, it appears that for patients receiving chemotherapy, radiation to the duodenum, or other drugs, the enterochromaffin cells of the mucosa of the duodenum lead to the release of 5-HT. When 5-HT, or serotonin, is released from these cells, it binds to specific 5-HT receptors and these afferent impulses travel to the VC.16,21

More recently, a new ligand-receptor pair has been described as having an important role in nausea and vomiting. The three neurokinin receptors are called neurokinin-1 (NK-1), neurokinin-2, and neurokinin-3 receptors. Their preferred ligands are known as neurokinins or tachykinins. These are 11-amino acid peptides including substance p, neurokinin A, and neurokinin B. The NK-1 receptor is stimulated by substance p and is thought to be involved with emesis.13,22

Causes of Nausea and Vomiting

There are numerous potential causes of nausea and vomiting in terminal cancer patients requiring palliative care. These are presented in Table 9–1 and are useful to remember when dealing with advanced disease. Reversible causes (e.g., constipation) may be found, and it is crucial to abolish nausea and vomiting as quickly as possible. Often, the cause for nausea and vomiting is multifactorial.14,16,20,23,24 For instance, there may be a physiological imbalance, such as a fluid and electrolyte imbalance, occurring at the same time as nausea is provoked by addition of opioids or nonsteroidal antiinflammatory drugs (NSAIDs) to control pain. In the 2-year experience of the World Health Organization with the analgesic ladder in cancer pain, nausea and vomiting were present in 22% of the days during the three-step treatment.22 It has recently been hypothesized that patients’ expectations may affect their expectations of symptom distress and experience of nausea and vomiting. One study examined chemotherapy-related nausea and vomiting in treatment-naïve patients and found a statistically significant relationship (p = 0.015) between the patient’s expectations of the symptom occurrence and their expectations of symptom distress.13,26 Roscoe and colleagues27 described two studies that found significant relationships between patients’ expectations for nausea development measured before their first chemotherapy treatment and their mean postchemotherapy nausea severity. Additionally, when considering nausea and vomiting from a QOL perspective (see Figure 9–1),11 psychological, social, and spiritual distress can cause or exacerbate nausea and vomiting.
Assessment of Nausea and Vomiting

Assessment is an important process and the foundation of all treatment-related decisions. It should be an ongoing process that begins with the initial patient contact regarding nausea and vomiting. Without a complete and ongoing assessment, nausea and vomiting may be mismanaged. This can result in unnecessary anxiety, suffering, and a decrease in QOL for the patient and family. Nurses working in all settings and with all age ranges of patients need to use skillful observation along with effective data collection techniques during assessment. It is rare that patients present with nausea and vomiting as a first sign of advanced cancer. Generally, patients who complain of this symptom complex have a well-documented history of their disease, including diagnosis, prior treatment, and sites of metastases. If this information is not available, nurses should obtain a complete medical/surgical history, including previous episodes of nausea and vomiting, effectiveness of previous treatments for this symptom complex, and any current treatment that might be contributing to these symptoms. Information obtained by questionnaires or self-report tools such as diaries, journals, or logs is crucial for the identification and management of this symptom complex and for improving the patient’s QOL.\textsuperscript{12,18,20}

Assessment and evaluation of nausea and vomiting also must include the pattern, what triggers the symptom complex, assessment of the mouth, assessment of the abdomen and bowel sounds, assessment of the rectum, possible laboratory studies (e.g., renal and liver function, ionized calcium, electrolytes, white blood cell count and differential, serum drug levels), and possible radiographic studies (e.g., computed tomography, magnetic resonance imaging scan, abdomen flat plate). Specifically, nurses should try to determine if there is a pattern to the nausea after certain drugs, after meals, on movement, in certain situations, or with certain smells. It is also important to ask if there is epigastric pain (possibly indicating gastritis), pain on swallowing (oral thrush), pain on standing (mesenteric traction), thirst (hypercalcemia), hiccups (uremia), heartburn (small stomach syndrome), or constipation.\textsuperscript{28}

There are several measurement tools that may be used to assess one or more of the components of nausea and vomiting. Some tools measure multiple components, while others measure a single component or a global measure of the nausea/vomiting. Instruments may involve checklists, visual analogue scales, patient interviews, or Likert scales. Almost all involve self-report by the patient.\textsuperscript{14,15,29–33} The most commonly used tools with reliability and validity are shown in Table 9–2.\textsuperscript{13,15,29,34,35}

Whatever tool nurses use should be evaluated and chosen carefully. The words on the tools should have the same meaning to all participants. It is also important not to burden the patient or family with lengthy or intrusive questions.\textsuperscript{13} Goodman\textsuperscript{36} provided examples of a chemotherapy treatment diary that could be adapted for use with terminally ill patients to record nausea and vomiting (Figure 9–3).

CNS = central nervous system; NSAIDs = nonsteroidal antiinflammatory drugs.
Teresa, a Patient with Acute Onset of Nausea

Teresa, a 34-year-old mother of two young children, is a hospice patient with metastatic ovarian cancer. She tells you she has had mild intermittent "stomach upset" with her pain medication but now states she has severe nausea. She feels like she will vomit but only has dry heaves. She currently has three 100 mcg/h transdermal fentanyl patches that are changed every 48 hours. She also uses oral transmucosal fentanyl citrate four times per day as needed for pain. She recently had to increase her dose from 400 mcg to 800 mcg four times per day. Teresa does not want to eat or drink fluids because of the nausea and dry heaves. You perform a thorough assessment of this new symptom by (1) asking the patient/family about the severity/intensity of the nausea, duration of nausea, frequency of nausea, pattern of nausea, triggers (e.g., with movement, after eating or...
drinking), and presence of vomiting; (2) asking the patient/family about epigastric pain, pain on swallowing, pain on standing, thirst, hiccups, heartburn, constipation, and any changes in medications; and (3) performing a thorough assessment of the abdomen and bowel sounds, and of the rectum.

Through your assessment you discover that bowel sounds are decreased in all quadrants, and the abdomen is firm and distended. The patient states that she stopped taking the stool softener and laxative because she thought it was causing her nausea and she does not remember the last time she had a stool.

You decide to prepare and give Teresa an enema of molasses, skim milk, and warm water and follow this by 8 ounces of warm water. The patient has a large bowel movement and agrees to restart a bowel regimen with Senokot-S. You choose this product because it has a stool softener and mild stimulant in one pill rather than the multiple pills the patient was taking previously. The hospice physician also prescribes 10 mg of metoclopramide every 6 hours, with additional 10-mg doses as needed for severe nausea. Within 3 days Teresa’s nausea and dry heaves are under control, she is having regular bowel movements, and she is able to take some fluids, food, and medications by mouth.

Pharmacological Palliative Management of Nausea and Vomiting

Progress has been made in managing chemotherapy-induced nausea and vomiting but not necessarily in nausea and vomiting experienced by patients with advanced disease requiring end-of-life care. The challenge is to provide appropriate antiemetic protocols for these patients in the setting in which they are receiving palliative care, while appreciating the demand for cost containment in health care delivery. Individuals with advanced cancer range from pediatric patients to elderly patients and receive end-of-life care in many health care settings (e.g., home, hospitals, inpatient hospice units, hospice houses, and outpatient and ambulatory units). The array of antiemetics available has increased (Table 9–3), allowing for individualized protocols. Thus, it is important for nurses to continually ask the patient and family about nausea and vomiting and the effectiveness of the treatment. Additionally, it is essential that nurses use nonpharmacological methods to prevent and decrease nausea and vomiting.

In recent years, health care associations and groups of health care providers have developed recommendations or guidelines for the use of antiemetics in clinical practice. However, only a few of these mention the use of antiemetics for terminally ill patients.22,37,40–42

According to Kaye28 the overall plan of management for palliative care of nausea and vomiting should be as follows:

1. Make an assessment.
2. Consider the causes.
3. Choose the antiemetic(s).
4. Choose the route.
5. Change the protocol if it is not working.
6. Consider steroids.
7. Consider ranitidine.
8. Decrease or change the opioid for pain.
9. Remember that anxiety can cause nausea.

Woodruff19 adds that pharmacological management should include adequate doses of antiemetics, combinations of antiemetics, and use of intravenous (IV) and rectal routes if necessary. If nausea and vomiting continue, consider psychological factors, reassess for missed physical causes, and try different combinations of antiemetics.

Successful pharmacological management of nausea and vomiting in advanced cancer is related to the frequency, dose, and type of antiemetic. Successful management is also related to providing antiemetics around the clock.

Classes of Antiemetics

There are currently 10 classes of drugs used as antiemetics in palliative care: butyrophenones, prokinetic agents, cannabinoids, phenothiazines, antihistamines, anticholinergics, steroids, benzodiazepines, 5-HT3 receptor antagonists, and NK1 receptor antagonists.

Mannix3 recommends seven steps to choosing an appropriate antiemetic protocol for palliative care. The first step involves identifying the likely cause(s) of the symptoms. In the second step, the healthcare professional should try to identify the pathway by which each cause is triggering nausea and vomiting (see Figure 9–3). In step three, it is helpful to identify the neurotransmitter receptor that may be involved in the pathway, such as the 5-HT3 receptor. Once the receptor is identified, step four requires selection of the most potent antagonist to that receptor. Step five involves selecting a route of administration that will ensure that the drug will reach the site of action. Once the route is chosen, step six is to titrate the dose carefully and give the antiemetic around the clock. Lastly, in step seven, if symptoms continue, review the likely cause(s) and consider additional treatment that may be required for an overlooked cause.

The clinical practice guidelines developed by the American Society of Clinical Oncologists (ASCO)40 provides levels and grades of evidence for the guidelines. The five levels of evidence include:

- Level I: Evidence is obtained from meta-analysis of multiple, well-designed, controlled studies.
- Level II: Evidence is obtained from at least one well-designed experimental study
- Level III: Evidence is obtained from well-designed, quasi-experimental studies such as nonrandomized, controlled, single-group, pre-post, cohort, time, or matched case-control studies
- Level IV: Evidence is from well-designed, nonexperimental studies, such as comparative and correlational descriptive and case studies
- Level V: Evidence is from case reports and clinical examples

<td>Dry mouth, blurred vision, sedation</td>
<td>Geriatric clients may be more sensitive to dose.</td>
</tr>
</tbody>
</table>

IM = intramuscular; SQ = subcutaneous; IV = intravenous; PR = per rectum; ICP = intracranial pressure; prn = as required; 5-HT = 5-hydroxytryptamine.

There are four grades in the ASCO guidelines. They are:

A: There is evidence of Level I or consistent findings from multiple studies of Levels II, III, and IV.
B: There is evidence of Level II, III, and IV, and findings are generally consistent.
C: There is evidence of types II, III, and IV, but findings are inconsistent.
D: There is little or no systematic empirical evidence.

Butyrophenones are dopamine antagonists (D₂ subtype) and are rated by the ASCO guidelines as Level I and grade A. Haloperidol and droperidol are the drugs in this class, and they are most potent at the CTZ (see Figure 9–3). Butyrophenones are major tranquilizers, whose mode of action, other than dopamine blockade, is not well understood. In general, these drugs are less effective at controlling nausea and vomiting than other drugs, except for the phenothiazines. They are effective, however, when used in combination with other drugs, especially with the 5-HT₃ receptor antagonists. Butyrophenones can be effective when anxiety and anticipatory symptoms aggravate the intensity of a patient’s nausea and vomiting. They can have severe side effects, including dystonic reactions, akathisia, sedation, and postural hypotension.³,13,19,22,36,40

Prokinetic agents (see Table 9–3) include metoclopramide and domperidone. ASCO rates these agents as Level I and grade A for nausea and vomiting. They are also called ‘substituted benzamides.’ Metoclopramide is the most commonly used drug in this category. It has some antidopaminergic activity at the CTZ and stimulates 5-HT₄ receptors, which helps to bring normal peristalsis in the upper gastrointestinal tract and to block 5-HT₃ receptors in the CTZ and gut. Extrapyramidal side effects are common. Infusing the drug over 30 minutes and administering diphenhydramine 25 mg to 50 mg at the same time may lessen these side effects. Metoclopramide also enhances gastric emptying, decreases the sensation of fullness caused by gastric stasis, decreases the heartburn caused by chemotherapy, and slows the colonic transit time caused by the 5-HT₃ receptor antagonists. Although initially used as a single agent, metoclopramide is now the main component of several combination protocols.³,13,19,22,40

Cannabinoids (see Table 9–3), such as dronabinol, are options for patients who are refractory to other antiemetics. These drugs presumably target higher CNS structures to prevent nausea and vomiting. According to the ASCO guidelines, there is Level I and grade A evidence that cannabinoids have antiemetic activity when used alone or in combination with other agents. Marijuana is the best known cannabinoid, but dronabinol is the plant extract preparation available for prescriptive use. The semisynthetic agents are nabilone and levonantradol. Marijuana, however, may be more effective. The actual site of action is not known but thought to be at the cortical level. Cannabinoids are especially helpful in younger adults who do not have a history of cardiac or psychiatric illness. Younger patients may have a more positive experience. Older adults tend to have more hallucinations, feeling ‘high’ and sedated, though these side effects may be decreased by low-dose phenothiazines. Because the central sympathomimetic activity may increase with the use of cannabinoids, these drugs should be used with caution in patients with hypertension or heart disease or in those who are receiving psychomimetic drugs.³,13,19,22,36,40,43,44

Phenothiazines (see Table 9–3) were once considered the mainstay of antiemetic therapy. The level of evidence for their use is rated I by ASCO and the grade is A. These drugs, like prochlorperazine and thiethylperazine, are primarily dopamine antagonists. They have tranquilizing as well as antiemetic effects. They have been used as single agents and in combination protocols. One advantage has been that they are available in several preparations (oral, rectal suppository, parenteral, and sustained-release preparation). The phenothiazines are especially effective for acute or delayed nausea. Because they have a different mechanism of action, they may be combined with 5-HT₃ receptor antagonists and dexamethasone. There is a high risk for extrapyramidal side effects (e.g., dystonia, akathisia, dyskinesia, akinesia). These symptoms appear to be greater in patients who are less than 30 years old. Frequently, 25 mg to 50 mg of diphenhydramine is given to prevent the extrapyramidal side effects.³,13,19,22,36,40,43

Antihistamines act on histamine receptors in the VC and on the vestibular afferents. Diphenhydramine is often used in combination protocols to minimize the development of extrapyramidal side effects. Cyclizine is less sedative than scopolamine (an anticholinergic) and can be given subcutaneously (SQ). These are rarely used as single agents for nausea and vomiting in palliative care, and the ASCO guidelines rate the level of evidence as II and grade as B.³,13,19,40,43

Anticholinergics currently are not used as frequently in antiemetic therapy. They do have an advantage in that they can be given sublingually, SQ, and transdermally. They have an anticholinergic effect at or near the VC. Parasympathetic side effects, like drying secretions, may sometimes be beneficial or troublesome because they cause dry mouth, ileus, urinary retention, and blurred vision. These drugs are effective at reducing peristalsis and inhibiting exocrine secretions and, thus, contribute to the palliation of colic and nausea.³,19

Corticosteroids, especially dexamethasone, are frequently a component of aggressive antiemetic regimens.³,13,19,22,45–47 The use of steroids remains controversial. They appear to exert their antiemetic effect as a result of their antiprostaglandin activity. Dexamethasone has an advantage because it is in oral and parenteral forms and is compatible in solution with 5-HT₃ receptor antagonists and metoclopramide. In general, corticosteroids are most effective in combination with other agents. The efficacy of ondansetron, granisetron, and metoclopramide can be enhanced by adding dexamethasone.⁴⁸ Use of corticosteroids for 4 to 5 days can prevent delayed nausea and vomiting. However, the dose should be tapered after several days to decrease or prevent insomnia, anxiety, euphoria, and other side effects common to corticosteroids. A trial of high-dose steroids should be considered if there is increased intracranial pressure, hypercalcemia, or malignant pyloric stenosis. They also should be tried for advanced cancer when nausea is resistant to other antiemetics.³,13,19,28,36,43,49 The ASCO guidelines suggest that the
level of evidence is II and grade is B for the use of single doses of corticosteroids.  

The site of action for benzodiazepines, like lorazepam (see Table 9–3), is the central nervous system. Lorazepam may be used alone but is commonly used in combination protocols. The ASCO guidelines recommend that benzodiazepines be used in combination regimens (level of evidence II and grade B). Additionally, lorazepam is a potent anxiolytic and amnesic. The temporary amnesic effect may be useful in patients with anticipatory nausea and vomiting. Malik and Khan found that lorazepam decreased the incidence of anticipatory nausea and vomiting as well as acute emesis. Pediatric patients may experience sedation and pleasant hallucinations. Lorazepam should be used with caution in debilitated patients or those with hepatic or renal dysfunction.

Since 1986, when the selective blockade of 5-HT1 receptors was shown to block vomiting associated with cisplatin, there has been a rapid creation of new drugs and increased knowledge of the sites and roles of 5-HT receptors. The 5-HT3 receptors have been discovered in the CTZ, in the VC (centrally), and in the terminals of the vagal afferents in the gut (peripherally). The activities of these 5-HT3 receptor antagonists (see Table 9–3), like ondansetron, granisetron, and dolasetron mesylate appear to be limited to serotonin inhibition. Therefore, the extrapyramidal side effects associated with dopamine antagonists are eliminated. Ondansetron was the first of these agents to become available in 1991, followed by granisetron in 1994, and dolasetron mesylate in 1997. Each of these drugs may be given orally or intravenously. The oral route is preferred when feasible for ease of use and cost. Granisetron is the most specific 5-HT3 receptor antagonist and has the highest potency and a longer duration of action than ondansetron. All of these medications can be given to children and the elderly and have few side effects. The ASCO guidelines state the level of evidence for these medications as effective single agents is I and the grade is A. Many clinicians feel that there are no major differences in the efficacy and toxicity of the three approved drugs in this category. Palonosetron is a pharmacologically distinct 5-HT3 antagonist that has recently been approved by the FDA. It appears to have 100-fold higher affinity for the receptor compared to ondansetron, granisetron and dolasetron. 

As previously discussed, there is a new ligand-receptor pair which has been described as having an important role in nausea and vomiting. This new class of drugs are called substance P antagonists or neurokinin-1 antagonists. Aprepitant is an oral drug that acts as an NK-1 antagonist. It has been shown to be effective with ondansetron and dexamethasone to prevent acute and delayed nausea and vomiting. There are some additional miscellaneous agents that may be helpful for terminally ill patients. Octreotide acetate is a somatostatin analogue. Thus, it mimics the actions of the natural hormone somatostatin and is long-acting. It may be helpful for nausea and vomiting associated with intestinal obstruction. Specifically, it inhibits gastric, pancreatic, and intestinal secretions and reduces gastrointestinal motility. Another agent is dimenhydrinate, which contains both diphenhydramine and chlorotheophylline. It is not known how dimenhydrinate alleviates nausea and vomiting. It is helpful for nausea, vomiting, and dizziness. There have been a few studies conducted with olanzapine for the relief of nausea in patients with advanced cancer and patients with delayed nausea. Olanzapine is currently indicated for schizophrenia and bipolar mania. Further research is needed to efficacy of this drug with terminally ill patients.

Combination Protocols

Currently, combining antiemetic drugs appears to improve efficacy, decrease side effects, and increase QOL. This practice is based on the theory that blocking different types of neurotransmitter receptors may offer better management of nausea and vomiting. In some instances, single agents, such as granisetron, ondansetron, and prochlorperazine, may be used for this symptom complex. However, the combination of a 5-HT3 receptor antagonist and a corticosteroid may be the most effective antiemetic regimen. The various agents used in combination are adjusted according to the individual’s tolerance to specific agents.

Routes of Administration

Nausea and vomiting may be treated with a combination of oral medications. If tolerated by the patient, this may be the most cost-effective treatment and provide the best prophylaxis because different drugs can attack from several sites and mechanisms of action. Unfortunately, other routes are needed if the patient has severe vomiting or is unable to swallow. If the patient has IV access, IV medications are appropriate. Some drugs may be given by intramuscular (IM) injection, but this can be painful and, thus, is usually avoided. Other options are to give drugs by a continuous SQ infusion, rectal suppository or tablet in the rectum, sublingually, or by a transdermal patch. A continuous SQ infusion is useful for severe nausea and vomiting, to avoid repeated injections. It is also important to remember non-drug methods in combination with antiemetic agents.

Nonpharmacological Palliative Management of Nausea and Vomiting

Some literature exists related to nonpharmacological management of chemotherapy-induced nausea and vomiting, but there is little current literature concerning nonpharmacological techniques for patients receiving end-of-life care. Nonpharmacological management of nausea and vomiting may involve simple self-care techniques (Table 9–4) or uniting the body and mind using psychological interventions to control physiological responses. There are many different nonpharmacological techniques available today that could be used for palliative management of nausea and vomiting.

Many nonpharmacological techniques used to control nausea and vomiting in patients with advanced cancer are classified
as behavioral interventions. This involves the acquisition of new adaptive behavioral skills. These techniques may include relaxation, biofeedback, self-hypnosis, cognitive distraction, guided imagery, and systematic desensitization. Other therapies that are gaining in popularity are acupuncture, acupressure, and music therapy (Table 9–4).13,55,56,58

Behavioral interventions can be used alone or in combination with antiemetic drugs to prevent and control nausea and vomiting. All of these techniques attempt to induce relaxation as a learned response. They differ only in the manner in which they induce relaxation.55

Behavioral interventions have been found to be effective for the following reasons: (1) they produce relaxation, which can decrease nausea and vomiting; (2) they serve as a distraction from the stimulus causing nausea and vomiting; (3) they enhance feelings of control and decrease feelings of helplessness as patients are actively involved in decreasing nausea and vomiting; (4) they have no side effects; (5) they are easily self-administered; and (6) they can be cost effective because they require limited time by a health care professional to teach these interventions.10,55,58,60 There is currently no definitive research that indicates which method is most effective; rather, it appears to depend on individual preference.

Self-Hypnosis

Self-hypnosis was the first behavioral technique tested to control the symptom complex of nausea and vomiting. This used to be considered a psychoanalytical approach in psychotherapy, but more recently has been categorized as a behavioral intervention. With this intervention, individuals learn to invoke a physiological state of altered consciousness and total-body relaxation. This results from the individual’s intensified attention receptiveness, and increased receptiveness to a specific idea.55,56 As with many of the behavioral techniques, there have been few controlled studies on self-hypnosis. Most of the research has been performed with children and adolescents because they are more easily hypnotized than adults.61–66 Additionally, this research has been with individuals receiving chemotherapy and not individuals with advanced cancer receiving palliative care.13 The results of the research have been mixed, with only some patients having a decrease in the frequency, severity, amount, and duration of vomiting as well as duration of nausea. Unfortunately, hypnotic methods are not standardized, but all include relaxation and relaxation imagery. The advantages include an absence of side effects, no need for equipment, minimal physical effort, and minimal training. Health care professionals, including nurses, have successfully taught patients self-hypnosis techniques.61,62 In a study by Marchioro and associates,66 all subjects showed a complete remission of anticipatory nausea and vomiting and major responses regarding postchemotherapy nausea and vomiting: however, these were not terminal patients. Research is desperately needed to evaluate which behavioral interventions are most effective in patients of all ages with advanced disease receiving end-of-life care.

**Progressive Muscle Relaxation**

Progressive muscle relaxation (PMR), also called active relaxation, involves individuals learning to relax by progressively tensing and then relaxing different muscle groups in the body. Passive relaxation is considered relaxation that does not involve active tensing of the muscles. Often, PMR is used in combination with guided imagery, and research has shown that it can decrease chemotherapy-induced nausea and vomiting as well as depression and anxiety.55,58,59,67–69 However, research has not been conducted on terminally ill patients receiving palliative care.13 When reviewing the research that has been performed on chemotherapy-induced nausea and vomiting, PMR has been shown to decrease the following: anxiety and nausea during chemotherapy, physiological indices of arousal (e.g., heart rate and blood pressure), anxiety after treatment, depression after treatment, and the occurrence of vomiting.69 One study60 was conducted with 60 Japanese cancer patients receiving chemotherapy protocols similar to those used in the United States. The subjects were randomly assigned to the PMR intervention or a control group. The findings verified the effectiveness of PMR in reducing the total scores used to measure nausea, vomiting and retching, and subjective feelings of anxiety. Another study71 was performed with Chinese breast cancer patients receiving chemotherapy to evaluate the use of PMR as an adjuvant intervention to pharmacological antiemetic treatment. The use of PMR significantly decreased the duration of nausea and vomiting in the experimental group as compared to the control group.

Interestingly, as many as 65% of patients who learned PMR while undergoing chemotherapy continued to use it even after chemotherapy.72 It can also be easily taught to health care professionals and to patients to apply on their own.59,73 However, there remains much to learn about the use of PMR with terminally ill cancer patients suffering from nausea and vomiting.
Biofeedback is a behavioral technique by which patients learn to control a specific physiological response (e.g., muscle tension) by receiving information about moment-to-moment changes in that response. Two specific types of biofeedback include electromyography (EMG) and skin temperature (ST). The purpose of EMG biofeedback is to induce a state of deep muscle relaxation from tense muscles. The purpose of ST is to prevent skin temperature changes that precede nausea and vomiting.55,59,62 Recently, research has shown that biofeedback may help individuals achieve a state of generalized relaxation.59,62,74,75 However, research has not shown EMG or ST biofeedback to be as effective as PMR alone or biofeedback with PMR at

decreasing chemotherapy-induced nausea and vomiting. Therefore, little definitive data exist regarding biofeedback as a behavioral technique for chemotherapy-induced nausea and vomiting and even fewer data to demonstrate that either EMG or ST is effective at decreasing this symptom complex with terminally ill patients.

**Guided Imagery**

Guided imagery allows individuals with nausea and vomiting to mentally take themselves away from their current site to a place that is relaxing. Individuals may choose a vacation spot, a safe place, a specific place at home, or any pleasant place. It is believed that when individuals imagine what they would usually feel, hear, see, taste, and smell at their pleasant spot, they can mentally block the negative conditioned stimuli from the cerebral cortex and prevent nausea and vomiting. It is possible that the body physiologically responds to the created image rather than to the negative conditioned stimuli.

Research has suggested that guided imagery, or visualization, can facilitate relaxation, decrease anxiety, decrease anticipatory nausea and vomiting, and increase self-control. Guided imagery has also been assessed in combination with music therapy. When the results were compared to the pretest measures of nausea and vomiting, the duration of nausea was shorter with music therapy combined with guided imagery than preintervention. Interestingly, the subjects’ perceptions of the occurrence of nausea remained unchanged. The degree of vomiting was also reduced significantly, and there was a trend toward a decreased duration of vomiting observed with the music therapy/guided imagery intervention. In a more recent study, patients who received guided imagery plus the standard antiemetic therapy exhibited a significantly more positive response to chemotherapy. Unfortunately, guided imagery did not have an effect on patients’ perceptions of the frequency of nausea and vomiting or the distress associated with these symptoms. The subjects did, however, express that they felt more prepared, in control, powerful, and relaxed when using guided imagery.

From the limited research, it appears that guided imagery may be most effective at decreasing nausea and vomiting associated with chemotherapy and only when it is combined with another nonpharmacological technique, such as PMR or music therapy. There is little research that has examined guided imagery alone or in combination with another behavioral technique for patients receiving palliative care. Certainly, oncology nurses could instruct patients with advanced cancer in all settings regarding guided imagery alone or with another technique.

**Cognitive Distraction**

Cognitive distraction is also known as attentional diversion. This behavioral technique is thought to act by focusing an individual’s attention away from nausea, vomiting, and the stimuli associated with these phenomena. Research has shown that simply distracting children and adolescents by video games can decrease anticipatory nausea and vomiting. Research with adults has demonstrated that cognitive distraction can significantly decrease postchemotherapy nausea, whether patients have low or high anxiety. Whether cognitive distraction, such as video games, would be effective at decreasing nausea and vomiting in patients receiving end-of-life-care requires further research. Certainly, it is worth discussing this technique with patients.

**Systematic Desensitization**

Systematic desensitization is a standardized intervention that has been used to counteract anxiety-laden maladaptive responses such as phobias. There are three key steps to the desensitization process. First, the individual is taught a response, such as PMR, that is incompatible with the current maladaptive response (e.g., chemotherapy-induced nausea and vomiting). After this first step, the individual and teacher create a hierarchy of anxiety-provoking stimuli related to the feared situation (events related to receiving chemotherapy such as driving to the clinic, entering the treatment room, and seeing the chemotherapy nurse). This hierarchy of anxiety-provoking stimuli range from the least to the most frightening. In the last step, the individual uses the alternative response while systematically visualizing the increasingly aversive scenes related to chemotherapy and nausea and vomiting.

Early studies demonstrated that systematic desensitization can be effective with anticipatory nausea and vomiting associated with chemotherapy. Specifically, systematic desensitization has decreased the frequency, severity, and duration of anticipatory nausea and vomiting. Additionally, systematic desensitization significantly decreased the duration and severity of posttreatment nausea. Research has also shown that this particular behavioral technique can be effectively implemented by a variety of trained health care professionals (e.g., nurses, physicians, and clinical psychologists). Currently, research supports the use of this technique as an inexpensive, effective, nonpharmacological treatment for chemotherapy-induced nausea and vomiting; but there is little research with health care professionals effectively implementing this as a palliative care technique. It is important for trained nurses to begin to teach this technique to patients who might benefit when terminally ill and suffering from nausea and vomiting.

**Other Nonpharmacological Interventions**

Acupuncture and acupressure are Eastern health care therapies that are gaining awareness in oncology nursing and palliative care. Acupressure is a form of massage that uses specific energy channels known as meridians. Tsubos are acupuncture/acupressure points. Tsubos are points of decreased electrical resistance running along the body’s energy pathways that form the meridian system. It is believed that stimulating the tsubo improves energy flow, affects organs distant from the area being stimulated, and positively affects emotions. Most studies have been performed with chemotherapy-induced nausea and vomiting and not as palliative care techniques for...
nausea and vomiting. Some studies have shown acupuncture on P6 (Neiguan point) to be effective at decreasing nausea and vomiting for 8 hours, and if acupressure is applied immediately after P6 acupuncture, there is a prolonged antiemetic effect. Agru and colleagues treated women receiving cisplatin with metoclopramide, dexamethasone, and diphenhydramine with and without acupuncture. Patients had a temporary acupuncture needle for 20 minutes during the infusion of chemotherapy and then a more permanent needle 24 hours after chemotherapy. Acupuncture did decrease the intensity and duration of nausea and vomiting, but the investigators commented that it was difficult to perform acupuncture in daily practice. Dibble and associates conducted a pilot study with women undergoing chemotherapy for breast cancer and reported that finger acupressure decreased nausea. An NIH Consensus Conference has stated that acupuncture for adult postoperative and chemotherapy-related nausea and vomiting is efficacious. Additionally, several reviews of acupuncture and acupressure have concluded that these are efficacious methods for relieving nausea and vomiting. One study has been conducted on terminally ill patients. Unfortunately, the investigators found that acupressure wristbands were ineffective at decreasing the intensity or frequency of nausea and vomiting. The investigators experienced difficulty in obtaining complete data and found subject recruitment a problem. Thus, studies on terminally ill patients need to be repeated and extended to confirm the usefulness of acupuncture or acupressure, even though research with terminally ill patients is difficult to conduct.

Music therapy has been used with patients to prevent or control nausea or vomiting. This involves the application of music to produce specific changes in behavior. The main objective in the past has been to influence the patient’s physiological, psychological, emotional, and behavioral well-being. Music therapy has most often been used in combination with other nonpharmacological techniques. Few studies have been conducted on the ability of music therapy to decrease nausea and vomiting in cancer patients. Most of the studies have not used music therapy as a single intervention and have assessed nausea and vomiting only related to chemotherapy. Frank and colleagues combined music therapy with guided imagery. The duration of nausea and the patients’ perceptions of the degree of vomiting were decreased; however, the patients’ perceptions of nausea did not change, and there was only a slight decrease in the duration of vomiting. Standley used music therapy alone as an intervention and assessed the effects on the frequency and degree of anticipatory nausea and vomiting, as well as vomiting during and after chemotherapy. The individuals who received the music intervention reported less nausea and a longer time before nausea began. Eezzone and colleagues evaluated whether a music intervention would decrease bone marrow transplant patients’ perceptions of nausea and number of episodes of vomiting while receiving high-dose chemotherapy. Significant differences were found, with the music therapy patients having less nausea and fewer episodes of vomiting. Generally, music such as classical, folk, pop, or jazz is best. The music should be quiet and should create a calm background rather than being disruptive. Music therapy is an intervention that can be initiated independently by nurses in all settings for all oncology patients and individualized for each patient. Additionally, music as an intervention for patients with advanced cancer receiving end-of-life care would require less time and energy to implement than relaxation or guided imagery and, therefore, may be less taxing for the terminally ill patient. Certainly, music therapy in combination with antiemetic therapy warrants further study as a way to significantly decrease the distressing symptoms of nausea and vomiting.

**Nursing Interventions**

Palliative care is by definition active total care, thus, it is essential that nurses provide active care to relieve nausea and vomiting for terminally ill patients. Some of the important palliative care interventions recommended by the National Comprehensive Cancer Network (NCCN) palliative care guidelines are to provide adequate symptom management, to let the patient know that comfort is one of the primary concerns, to anticipate patient and family needs, to involve the family in care, and to educate the patient and family. As discussed in this chapter, the NCCN guidelines include the need to continue to assess and to treat symptoms and quality of life to determine if the status warrants changes in interventions. This is a key role that nurses should play related to nausea and vomiting in terminally ill patients.

Based on the current lack of literature on palliative care for symptoms such as nausea and vomiting, it is vital that nurses in all settings (e.g., administrators, clinicians, educators, and researchers) lead the way in learning how to manage these symptoms appropriately for terminally ill patients. From a clinical perspective, nurses need to provide initial and ongoing assessment of the patient’s symptom experience, implement appropriate drug and nondrug interventions, evaluate all interventions, and provide patient and family education. Administrators play a key role in providing the resources necessary for clinical nurses to give quality, but cost-effective, palliative care in all settings (hospitals, inpatient hospice units, hospice houses, homes, and outpatient/ambulatory units).

Family caregivers are also involved with managing nausea and vomiting, as with all aspects of end-of-life care. They often are responsible for overall symptom management, emotional support, support of daily activities, administering medications, providing nutrition, and performing other aspects of care. Additionally, the family is frequently the communication link between the patient and the nurse. Nurses depend heavily on family members for information about patients, especially when patients deteriorate. Thus, it is essential that family be involved in any education given to the patient. Education is an important tool for family members to have if they are to function effectively as a team.

First, patients and family need to be taught how to systematically assess the patient’s nausea and vomiting. They may use a log, such as the one developed by Goodman (see Figure 9–3).
It is helpful to teach the patient and family members to rate the distress caused by these symptoms on a scale of 0 to 10. This provides more accurate information regarding the intensity and/or relief of symptoms. The patient and family need to be taught problem-solving skills for specific situations (e.g., when they can give an extra dose of antiemetic) and self-care activities (see Table 9–4). The importance of taking antiemetics on a schedule and as prescribed should be reinforced. Information regarding medications and instructions for self-care should be provided in written form. Specific instruction should be given as to when to call the physician or nurse. Lastly, it is helpful to teach nonpharmacological methods for decreasing nausea and vomiting (e.g., music therapy or relaxation).

Nurse educators must begin to incorporate end-of-life issues and symptom management for terminally ill patients into the nursing curriculum and into textbooks. Educators can work collaboratively with clinicians to develop educational tools for patients and families (pamphlets, videos, and audiotapes). Additional research is desperately needed regarding appropriate antiemetic regimens, nonpharmacological interventions, appropriate self-care activities, and QOL issues for patients receiving palliative care. Nurse researchers can be actively involved in this research and in the dissemination of the results to clinicians and educators. Nurse researchers should design studies using prospective, longitudinal models, adequate sample sizes, and appropriate control groups. Findings should be reported in terms of clinical and statistical significance. Through collaborative efforts, nurse administrators, clinicians, educators, and researchers can help to decrease the incidence of nausea and vomiting and improve the QOL of terminally ill patients.

Case Study 2

VA, a 62-Year-Old Man Who Wants to Be at Home

VA, a 62-year-old man with metastatic lung cancer, is admitted to a palliative care unit because his family ‘can no longer care for him at home.’ He has severe bone pain, severe nausea, anorexia, anxiety, and panic attacks. He has told the hospice team and his family that he wants to be at home when he dies. He currently has three 100-mcg fentanyl patches placed every 3 days and takes two hydrocodone (7.5-mg hydrocodone with 750-mg acetaminophen) tablets every 3 to 4 hours for breakthrough pain. VA takes one prochlorperazine every 8 hours as needed for nausea. He has nothing prescribed for anxiety. You do a thorough assessment of his pain, nausea, and anxiety and learn the following: (1) his persistent pain is a 6 to 9 out of 10, his breakthrough pain level is 8 to 10 out of 10, his fentanyl patches give pain relief for 48 to 52 hours (pain level decreases to 2 to 3 out of 10 for the first 40 hours of the patch), his nausea is a 10 out of 10; (2) many years ago, he had learned transcendental meditation but has not practiced in 20 years; (3) his anxiety and panic attacks are precipitated by planning his funeral and will; (4) he is ‘allergic’ to morphine; and (5) he refuses anything for pain, nausea, or anxiety that will involve needles or invasive procedures.

After a hospice-team discussion and talking to the patient and family, several changes are made. The order for the fentanyl transdermal patch is changed to three 100-mcg patches every 48 hours. The hydrocodone tablets are changed to fentanyl oral transmucosal fentanyl citrate (Actiq). This is started at 200 mcg orally four times per day as needed for breakthrough pain and titrated upward to 600 mcg. Prochlorperazine is changed to metoclopramide 10 mg P.O. every 6 hours around the clock, with an additional 10 mg as needed for severe nausea. Dexamethasone is added at 4 mg P.O. three times per day to help with nausea and anorexia. Lorazepam is ordered at 1 mg P.O. every 6 hours as needed for anxiety. Additionally, you teach VA and his family how to use PMR with imagery. After 3 days, the patient’s persistent pain level has decreased to 2 to 4 out of 10, breakthrough pain level has decreased to 1 to 3 out of 10, nausea has decreased to 3 to 4 out of 10, and he is taking lorazepam only once per day for anxiety. Additionally, VA is using PMR and imagery with the help of his family three times per day, and his family decides to take him home.

Conclusion

A major goal of palliative care is to improve QOL by decreasing undue suffering. This can be achieved through symptom management, such as adequate treatment of nausea and vomiting in terminally ill patients. It is often difficult for nurses to meet the challenge of providing palliative care when there is a limited amount of research or literature to guide interventions for symptom management. This body of research and literature is growing but significantly less than the information available related to symptom management for patients receiving active cancer treatment. Nurses in all settings (e.g., administrators, clinicians, educators, and researchers) need to help increase our knowledge base and skills in the areas of symptom management and QOL issues for patients receiving end-of-life care. Vigilant assessment, appropriate use and evaluation of pharmacological and nonpharmacological interventions, appropriate patient and family education and support, and further research can accomplish this. Nausea and vomiting profoundly affect all aspects (physical well-being, psychological well-being, social well-being, and spiritual well-being) of an individual’s QOL, especially at the end of life. It is essential that nurses meet the challenge to improve QOL for patients with advanced disease by decreasing or abolishing nausea and vomiting.

Dysphagia, Xerostomia, and Hiccups

It seems ridiculous that with everything else going on, that what bothers me the most is my difficulty swallowing and my dry mouth. Can you help this?—Mark, 53-year-old ALS patient

- **Key Points**
  - Dysphagia, dry mouth, and hiccups affect social interaction and cause unnecessary suffering.
  - Dysphagia has many etiologies and a multitude of management options.
  - Xerostomia is a common complaint.
  - Hiccups, though seemingly harmless, can be extremely frustrating for patients and can be difficult to treat.
  - Comprehensive and regular mouth care relieves suffering and promotes comfort.

Dysphagia and dry mouth are disturbing symptoms that occur frequently in progressive terminal illness. Hiccups, while less frequent, can be as distressing, adversely affecting quality of life. These problems impact the essence of pleasurable activities such as food, communication, intimacy, social interaction, as well as nutrition.

In a culture where food is both the core of life and a central focus of one's daily structure, disinterest in food and lack of the ability to eat can cause distress for both patients and families. Patients lose interest and then withdraw from social interaction. Families, with all good intentions, keep focusing on food. This creates a tension that may make the situation worse because the focus shifts from the patient to the importance of food. Thus, care for patients with terminal illnesses who are experiencing dysphagia, hiccups, or dry mouth should focus on the following principles: (1) the patient and family are the unit of care, (2) relief of suffering is the primary goal, and (3) care is best delivered with a plan that reflects the underlying aspect of the life-threatening disease.¹

**DYSPHAGIA**

**CASE STUDY**

**TM, a Patient with Advanced Parkinson's Disease**

TM, a 74-year-old retired chef, was diagnosed with Parkinson’s disease in his mid 60s. His symptoms began with the classic small-amplitude intention tremor of his right hand, which was successfully treated with levodopa. Over the years, his overall status declined slowly, to the point that he developed a shuffling, festinating gait, with difficulty getting up from a chair and walking unassisted. His speech and voice function became increasingly marked by overall weakness of the muscles of articulation, with hypokinetic dysarthria and
impaired speech intelligibility, hypophonia (reduced vocal loudness), and a masked facial appearance. He gradually lost his independence with activities of daily living and required assistance for dressing, bathing, and even feeding himself. Furthermore, the weakness of the oral articulators had an impact on chewing and swallowing. Over the past year, TM began to hold food in his mouth for extended periods of time before he would begin the process of mastication. His chewing was slow and deliberate paired with his weak tongue muscles, and increasingly he would drool while eating. TM gradually began to lose weight, became more sedentary, and was markedly depressed at the loss of his functional independence.

TM’s wife became increasingly concerned about her husband’s declining status, especially the onset of coughing and choking while drinking and eating. Her concern was amplified by the need for a hospital admission for the third pneumonia in 6 months. This last admission prompted a referral to the speech language pathologist to evaluate TM’s swallowing safety. The evaluation findings revealed a cachectic and reserved gentleman who displayed considerable weakness of the lips, jaw, and tongue muscles, with drooling at rest. His face was expressionless and his voice was low in volume and gurgly in quality. He was unable to control liquids in his mouth, and mastication of solid foods was slow and disorganized. He coughed weakly and inconsistently while drinking thin liquids—both signs highly suspicious for aspiration. It was clear TM had been struggling with eating and swallowing for a long time. Swallowing inefficiency and aspiration of liquids were confirmed on videofluorographic examination. TM showed a moderate decrease in aspiration on thicker consistencies of liquids and soft foods, but it was clear that the effort it would take to meet his nutritional needs would be immense for both he and his family. This episode of pneumonia had increased the rigidity of his extremities and exacerbated his oral weakness. He was minimally communicative. The findings of the examination were discussed with TM and his family. Given his poor pulmonary clearance, there was a high likelihood that the aspiration pneumonia would recur if he were to continue to eat by mouth, perhaps even requiring a repeat hospitalization. An alternative was artificial nutrition and hydration.

During the months preceding his latest functional decline, TM and his family had discussed his wishes for nonoral nutrition, wishes that he had communicated with his primary care team. He wanted to proceed with eating by mouth, understanding the risks. He did not wish to have a gastrostomy tube placed. A plan was devised with TM’s wife to continue to feed him by mouth, acknowledging the inherent risks. The goal was to keep him comfortable: small, frequent meals with favorite foods; small sips of water before and between meals to decrease oral dryness; crushed medications given in applesauce or with thickened liquids; upright positioning during “mealtimes.” His wife was taught how to complete these tasks. Eventually, TM’s oral intake diminished to a teaspoon of pureed foods here and there, although he lost his desire for water. Over the next few weeks, TM’s pulmonary status deteriorated, so much so that supplemental oxygen and morphine were required because of difficulty breathing. The family opted not to treat the recurrent pneumonias, and eventually TM passed away at home in the care of his family, who upheld his wishes to avoid artificial hydration and nutrition.

Definition

Dysphagia is defined as difficulty swallowing food or liquid. Typically, chronic difficulty swallowing affects the efficiency with which oral alimentation is maintained. In addition, airway protection or swallowing safety can be threatened. Patients may complain of food getting caught along the upper digestive tract anywhere from the throat to the esophagus. In addition, diversion of food or liquid into the trachea may occur, causing aspiration, choking, or, in severe cases, asphyxiation. Chronic difficulty swallowing can be both frustrating and frightening for patients. Because nutrition is compromised, generalized weakness, appetite loss, and weight loss may ensue. In severe cases, malnutrition may occur. Aspiration pneumonia may also occur, causing fevers, malaise, shortness of breath, and, rarely, death.

The psychological impact of dysphagia cannot be underestimated. Eating or eating enough becomes a focus of care in the chronically ill patient and is more evident in terminally ill patients with dysphagia. Since the essence of nurturing is intertwined with the ability to provide and receive nourishment, the chronically ill patient, isolated from social interactions that take place around the consumption of food, becomes increasingly depressed. Caregivers often feel that nourishment is the one area in which they have had some opportunity to nurture their loved one in the past. When this is no longer available to them, the palliative care challenge in managing dysphagia is how to ensure comfort, even at the expense of optimal nutrition and hydration. Understanding the physiology of normal and aberrant swallowing is critical to meeting this challenge.

Physiology and Pathophysiology of Swallowing

Normal Swallowing

Swallowing involves the passage of food or liquid from the oral cavity through the esophagus and into the stomach, where the process of digestion begins. Swallowing is an extremely complex physiological act, and demands exquisite timing and coordination of more than 30 pairs of muscles under both voluntary and involuntary nervous control. Because humans swallow hundreds of times per day and are largely unaware of
the activity, it is remarkable that difficulties do not occur more frequently.

For purposes of discussion, the act of swallowing is divided into three stages (Figure 10–1). In reality, these stages occur simultaneously. The act of swallowing takes less than 20 seconds from the moment of bolus propulsion into the pharynx until the bolus reaches the stomach. The longest phase comprises the transit of the bolus through the esophagus.

The first stage of swallowing (see Figure 10–1A), the oral stage, is responsible for readying the bolus for swallowing. Bolus preparation is under voluntary control and can be halted or changed at any point. The primary activities of mastication include gathering and placement of semisoft and liquid boluses on the tongue. It is during this stage that one takes pleasure from the flavor and texture of food through the chemoreceptors of the tongue and palate. The duration of the oral stage is variable, depending on the viscosity or consistency of the food bolus and individual chewing styles. During mastication, the tongue moves the bolus to the dental arches to grind into smaller pieces. Opening the jaw as well as rotary and lateral movements achieves the masticatory process. Cohesive solid bolus formation is dependent on several factors: the presence of enzyme-rich saliva to bind the material together, the ability of the tongue to gather particles from the sulci of the cheek and the mouth floor, the prevention of food falling out of the oral cavity anteriorly, and the premature spilling into the pharynx.

Once the bolus is prepared and ready for swallowing, it is positioned on the blade of the tongue and propelled into the pharynx (see Figure 10–1B). Contact with the tongue occurs laterally on the hard palate and anteriorly on the central incisors. The soft palate then elevates, permitting the bolus to enter the pharynx, while closing off the nasopharynx, to prevent regurgitation of the bolus into the nose. The floor muscles of the mouth contract as the tongue base depresses, forming a chute down which the bolus can flow. Through a series of contractions by the intrinsic tongue muscles pressed against the hard palate, the torpedo-shaped bolus is propelled

**Figure 10–1.** Stages of swallowing, beginning with voluntary initiation of the swallow by the tongue (A), oral transit (B), pharyngeal stage of swallowing with airway protection (C) and (D), and esophageal stage (E). Source: Logemann (1998), reference 2.
in a rolling motion from anterior to posterior into the pharynx. Depending on the consistency of the bolus, this stage lasts approximately 1 second.

The second stage of swallowing, the pharyngeal stage (see Figure 10–1C/D), is elicited as the posterior movement of the tongue and passage. The bolus passage stimulates the sensory impulses of the glossopharyngeal and vagus nerves, which travel to the afferent swallowing center located in the lower medulla of the brain stem and then to the cortex. The pharyngeal and oral transit stages are closely associated. The oral cavity and the pharynx become one continuous tube with the entrance to the larynx closed off.1 The pharyngeal stage of swallowing is the most complex, requiring the most precise timing and coordination. It is during this stage that the airway is protected and the upper esophagus opens to accept the bolus.

The process of airway protection, that is, closure of the airway, is quite remarkable and intricate. There are several aspects of airway protection. Respiration ceases for up to 2.5 seconds, with an average of 0.3 to 0.6 second for a single sip of liquid.2,3,4 Swallowing usually occurs during the expiratory stage of the respiratory cycle, with expiration preceding and following the swallow. Laryngeal closure occurs from inferior to superior so that if material is present in the laryngeal entrance, it will be extruded into the hypopharynx during the swallow. As the floor of the mouth/tongue muscles contract to propel the bolus from the oral cavity, the larynx moves upward, closing the laryngeal vestibule. The vocal folds adduct simultaneously, and the epiglottis begins to invert over the entrance of the larynx, further protecting the airway. Opening of the upper esophageal segment is the result of traction of the cricoid cartilage and larynx away from the posterior pharyngeal wall as the suprahyoid muscles contract, pulling the larynx upward and forward.5–8 The greater the excursion of the larynx, the larger the diameter of the opening of the upper esophagus becomes.7 This movement creates a negative pressure in the esophagus, helping to propel the bolus toward the distal esophagus.

As the bolus enters the pharynx, its tail is driven toward the hypopharynx and esophagus by the positive pressure generated from the base of the tongue contacting the pharyngeal walls. The pharyngeal constrictor muscles contract sequentially, and their topographic arrangement has the effect of stripping the bolus through the hypopharynx and clearing the pharyngeal recesses. The duration of the pharyngeal stage of swallowing is approximately 1 second. The order of contraction of muscles is invariant, but the timing of contraction depends on the viscosity and size of the bolus.5–7 The biomechanical events involved in this stage of swallowing are under involuntary control and carefully sequenced in a pattern by the central swallowing center in the lower medulla. In the medulla, sensory feedback continuously modulates the motor response. For example, if the bolus is dense, the firing of a particular group of muscles of the tongue may be increased, or the opening of the upper esophagus may last longer with a large bolus volume. If the sensory feedback loop is disturbed, the onset of the pharyngeal stage of swallowing may be delayed or, in severe cases, absent.2,3,6

The esophageal stage or final stage of swallowing (see Figure 10–1E) involves transport of the bolus from the upper esophageal segment, through the lower esophageal segment, and into the stomach, a distance of approximately 25 cm.2,10 The esophageal stage is coordinated with the pharyngeal stage, with continued sequential contraction of muscles in the cervical esophagus. Like the pharyngeal phase of swallowing, the esophageal stage is under involuntary neuromuscular control. Unlike the pharyngeal stage, however, the speed of propagation of the bolus is much slower, with a rate of 3 to 4 cm/second compared to 12 cm/second in the pharynx.7 The upper esophagus consists of approximately 8 cm of striated skeletal muscle, beginning at the upper esophageal segment. The outer fibers of the cervical esophagus are arranged longitudinally, while the inner fibers are arranged in a circular configuration. As the bolus reaches the esophagus, the longitudinal muscles contract, followed by contraction of the circular fibers, constituting the primary peristaltic wave. The primary wave carries the bolus through the lower esophageal sphincter in a series of relaxation–contraction waves. The lower esophageal sphincter remains open until the peristaltic wave passes. A secondary peristaltic wave is generated where the striated muscle meets the smooth muscle and clears the esophagus of residue. This wave is reflexive in nature and initiated by distention of the esophagus during the primary peristaltic wave.3,9 After passage of the bolus, the upper and lower esophageal sphincters contract to their baseline tonic posture. This contains the gastric contents within the stomach and prevents regurgitation of material into the hypopharynx and airway.6

Pathophysiology of Swallowing

Difficulty swallowing can occur during, within, or across any of the above-described stages, depending on the underlying disease. Evaluation and treatment of dysphagia is dependent on a thorough understanding of the underlying aberrant anatomical and physiological components. It is helpful to conceptualize the process of bolus transfer through the oral cavity according to a piston–chamber model proposed by McConnell and Cerenko in 1988.4 The oral cavity, or chamber, comprises the area extending from the lips anteriorly to the hard palate superiorly and the pharyngeal wall posteriorly, bounded by the floor of the mouth inferiorly.

The tongue acts as the piston that creates pressure on the bolus to drive it into the esophagus. The ability of the oral cavity to fulfill its function as a closed chamber depends on the integrity of a number of muscular contractions, which form valves that open and close and are illustrated in Figure 10–2.10

Bolus flow, and, hence swallowing, is affected if there is dysfunction in the chamber or the piston. If the chamber leaks, residue, regurgitation, or aspiration may occur. Inefficient bolus flow results from weakness in the tongue-driving force on the bolus or reduced contraction of the pharynx. Patients with muscle weakness due to stroke, degenerative neuromuscular disease, or neoplastic lesions involving motor and sensory function of the lips and face may experience difficulty containing the
bolus in the oral cavity, producing drooling. Patients with severe dementia who are not aware of food in their mouth may fail to close their lips. In the presence of facial weakness, for example, patients with Parkinson's disease or ALS, the boluses may pocket in the lateral buccal sulci, making retrieval difficult, especially if buccal and lingual weakness coexist. In cases of reduced sensation, pocketed food may remain in the oral cavity for several hours, possibly increasing the risk of aspiration. Nasal regurgitation of liquids and particles of solids occurs when the velopharyngeal port is dysfunctional. This is common in both palate cancer if treatment has involved resection and in patients with progressive neuromuscular disease. Weak tongue-driving force during swallowing results in a significant amount of residue in the pharyngeal recesses, loss of control over the bolus, or incomplete laryngeal closure, causing aspiration before, during, or after the swallow.

Valving of the larynx during the swallow is important for prevention of aspiration into the tracheobronchial tree. Failure of the larynx to close due to timing or muscular incompetence can result in aspiration of liquids or solid materials. Reduced sensory function and weakened laryngeal musculature impair expectoration of aspirated material. Functional and reliable laryngeal valving is crucial not only during oropharyngeal swallowing but also during periods of gastroesophageal reflux, regurgitation, or emesis. Failure of the upper esophagus to open completely results in residue in the pyriform sinuses superior to the pharyngoesophageal segment and, if abundant, may spill over into the unprotected larynx and trachea.

Prevalence and Impact

A multitude of diseases can affect the “chamber–piston” relationship, causing dysphagia, particularly in patients receiving palliative care. These include degenerative neuromuscular diseases, progressive cognitive decline disorders, recurrent or fatal neoplastic nervous system or gastrointestinal obstructive lesions, or pervasive debilitation from multisystem decline. In some cases, side effects of treatment including radiation therapy or chemotherapy, are the precipitating causative factors of dysphagia, whereas in other cases, the progressive nature of the disease leads to unsafe and inefficient swallowing.

Understanding the physiological impact of the illness is critical in evaluation of the swallowing disorder and the method of management. For example, generalized weakness of the oropharyngeal musculature may be evident in two patients, one with a diagnosis of ALS who requires mechanical ventilation, and one who has undergone further chemoradiation therapy for a recurrent neck squamous cell carcinoma. In the patient with ALS, the likely rapid progression would avoid the suggestion of effortful swallows as a compensatory strategy to clear boluses through the pharynx while swallowing due to fatigue. On the other hand, in the patient with neck cancer, encouraging effortful swallows to preserve motor flexibility may assist in protecting his airway to enable him to take some food by mouth in the short term. The proceeding recommendations describe some commonly encountered etiological categories and their impact on swallowing.

Neoplasms

Tumors involving the nervous system as well as the head and neck and upper aerodigestive tract can interfere with swallowing.

Brain Tumors. Brain tumors are classified into primary and secondary types. Primary brain tumors are a diverse group of neoplasms arising from different cells of the central nervous system. In contrast, secondary tumors originate elsewhere in the body and metastasize to the brain.

It has been estimated that 34,000 new cases of primary brain tumors, malignant or benign, are diagnosed each year. Although dysphagia is rarely the presenting symptom, swallowing problems can develop as the tumor increases in size and compresses surrounding structures. The corticobulbar tracts involved in coordinating both the oral and pharyngeal stages of swallowing may be affected.

Extrinsic tumors located around the brain stem, such as acoustic neuromas and meningiomas, as well as those originating in the skull base, such as glomus jugulare, glomus vagale tumors, and chordomas, may compress or invade the lower medulla. Hence, the cranial nerves and their nuclei that are critical for swallowing will be affected, with the specific swallowing impairment dependent upon which cranial nerves are affected. Compromise of the glossopharyngeal, vagus, and hypoglossal cranial nerves singly or in combination results in
the greatest swallowing dysfunction. The relative inaccessibility of these tumors for treatment is associated with recurrence, which, in turn, can result in increased cranial nerve and swallowing impairment. In addition to direct tumor effects, swallowing may be indirectly affected by depressed levels of consciousness and reduced awareness that is associated with tumor progression and treatment effects.

**Head and Neck Cancer.** Oropharyngeal dysphagia is almost synonymous with advanced stage head and neck cancer because the vital structures involved in swallowing can be impaired by the tumor, as well as by treatment. Head and neck tumors are located in a variety of sites in the oral cavity, including the bony structures, the lips, floor of the mouth, tongue, palate, and tonsillar fossa, as well as the hypopharynx, larynx, and nasopharynx. Treatment of head and neck neoplasms varies according to cell type, location, tumor size, and presence of neck metastases. In the past decade, treatment for locally advanced head and neck cancer has shifted from primary surgical resection to an “organ-sparing” approach whereby chemoradiation therapy is the primary treatment and salvage surgery is reserved for recurrent disease. This is most evident in patients with laryngeal cancer because of the morbidity associated with surgical resection of the larynx or laryngectomy. However, even with the goal of organ preservation, significant speech and swallowing dysfunction can occur.

Many patients with advanced head and neck cancer are unable to resume oral nutrition as a result of the surgical resection or secondary radiation or chemotherapy treatment. Subsequent side effects include mucositis in the acute stage, as well as muscle fibrosis, scarring, and dry mouth, even after the completion of treatment. Some patients manage to compensate for their dysphagia with changes in posture or diet consistencies suggested by speech language pathologists or nutritionists. Other patients rely on oral nutritional supplements delivered by mouth or gastrostomy tube. In any case, by the time the patient with advanced head and neck cancer reaches the terminal stage, he or she has already been coping with dysphagia and its very visible consequences for many months.

**Malignant Esophageal Tumors.** The incidence of malignant esophageal tumors is approximately 3 to 4 per 100,000. Symptomatic presentation of dysphagia usually occurs late in the disease, resulting in diagnosis of advanced malignancy. Esophageal carcinoma can arise either from squamous cells of the mucosa or as adenocarcinomas of the columnar lining of Barrett’s epithelium. Patients commonly complain of weight loss and progressive dysphagia with solid foods rather than liquids. In some cases, intractable cough may indicate extension of the tumor to the mediastinum or trachea. The presence of local extension to the aorta, trachea, or other mediastinal structures eliminates the possibility of surgical resection. Survival rates are reported to be between 10% and 20% at 5 years, and thus, palliative care is the foundation of management for this disease.

If diagnosed early, esophagectomy or esophagogastrectomy may be the treatment of choice. However, in cases of unresectable advanced disease, symptomatic relief of dysphagia may be accomplished by radiation therapy, esophageal dilation, yttrium-argon-garnet (YAG) laser electrocautery, chemotherapy, or placement of an esophageal stent to open the lumen of the esophagus. Each of these treatments is associated with considerable side effects, including radiation-induced esophagitis and chemotherapy-induced mucositis. Esophageal perforation during laser surgery or dilation and migration of the esophageal stents are potential complications from palliative procedures. Frequently, jejunostomy tubes must be placed for nonoral feeding.

**Progressive Neuromuscular Diseases**

**Amyotrophic Lateral Sclerosis.** Amyotrophic lateral sclerosis, or ALS, is encountered with unfortunate regularity in patients on a palliative care service. A rapidly progressive degenerative disease of unknown etiology, ALS involves the motor neurons of the brain and spinal cord. One quarter of ALS patients present with difficulty swallowing as their initial complaint, while other patients begin with distal weakness that travels proximally to involve the bulbar musculature. As the disease progresses, there is involvement with upper and lower motor neurons and the respiratory system in the later stages. Respiratory failure is the usual cause of death in patients with ALS because of weakness in diaphragmatic, laryngeal, and lingual function.

Typically, patients with ALS also experience a reduction in tongue mobility, affecting the ability to lateralize food for chewing and to control material in the mouth. With disease progression, heavier foods, even pureed, are difficult to manipulate, resulting in significant residue in the oral cavity and hypopharynx. With oral musculature weakening, several conditions occur: nasal regurgitation of fluids and loss of control over liquids, resulting in aspiration and coughing before the swallow is triggered. Speech impairment parallels swallowing difficulty, affecting communication as well as alimentation. Diet modifications with calorie-dense foods and postural alterations are necessary if oral intake is to continue. However, many patients reach a point where the effort involved in eating is too great and the pleasure is lost. If the patient chooses, a gastrostomy tube is placed percutaneously to provide nutrition, and sometimes supplemental oral intake for pleasure is possible. Parkinson’s Disease. Parkinson’s disease is a relatively common, slowly progressive disease of the central nervous system, marked by an inability to execute learned motor skills automatically. A classic triad of symptoms, resting tremor, bradykinesia, and rigidity, accompanies Parkinson’s disease. An imbalance between dopamine-activated and acetylcholine-activated neural pathways in the basal ganglia causes the symptoms. The largest etiological group is idiopathic, however, Parkinson-like symptoms may occur as a result of medications, toxins, head trauma, or degenerative conditions.
Dysphagia in Parkinson's disease is related to changes in striated muscles under dopaminergic control and in smooth muscles under autonomic control. The oral stage is associated with rigidity of the lingual musculature rather than weakness. Small-amplitude, ineffective tongue-rolling movements are observed as patients attempt to propel the boluses into the pharynx. As a result, pharyngeal swallow responses are delayed, with aspiration occurring before and during the swallow. Expectoration of cough-aspirated material is weak because of rigidity of the laryngeal musculature. Incomplete opening of the upper esophageal sphincter and esophageal dysmotility are also commonly observed in patients with Parkinson's disease.

In the early stages, antiparkinsonian medications such as levodopa improve flexibility and speed during swallowing. However, pharmacotherapy has only a limited amount to offer dysphagic patients with severe symptoms and sometimes nonoral feeding is necessary. Pneumonia is one of the most prevalent causes of death in patients with Parkinson's disease, irrespective of whether the patients are fed orally or via a feeding tube.

**Multiple Sclerosis.** Swallowing difficulty is uncommon in the early stages of multiple sclerosis. The scattered inflammatory white-matter lesions observed in the central nervous system result in varying combinations of motor, sensory, and cognitive deficits, which usually run a remitting–relapsing course. Swallowing problems are less common in this disease, occurring in the end stages in approximately 10% to 33% of cases. Difficulties arise with respect to the feeding process because of hand tremors and spasticity. Sclerosed plaques can be found in the cortex and the brain stem and can affect cranial nerves. Therefore, swallowing dysfunction will depend on the location of the lesions.

Sometimes the swallowing dysfunction is mild and goes unnoticed by the patients. In patients who complain of dysphagia, the most commonly observed symptoms are delayed oropharyngeal swallowing initiation, reduced tongue strength, and weak pharyngeal contractions. These result in pharyngeal residue after the swallow and a sense of food getting caught in the throat.

A coexisting feature of multiple sclerosis in the later stages is cognitive decline and dementia. Patients may be unaware of the act of eating and may be dependent on being fed. Family and caregivers require specific information to help patients compensate for reduced awareness.

**Dementia**

Dementia can result from several causes, including cumulative brain damage from multiple small cerebral infarcts in patients with hypertension and diabetes, Alzheimer’s disease, advanced stages of other diseases such as Parkinson’s or Huntington’s disease, or multiple sclerosis. In addition, patients can demonstrate cognitive decline from chronic metabolic derangement, sedating medications, and/or depression. Patients with dementia frequently encounter pneumonia, particularly in the advanced stages of the disease.

Dementia causes fluctuating attention span, inactivity, agitation, confusion, and memory loss. These symptoms may necessitate medications to calm the wandering, agitation, and somnolence. Decreased consciousness predisposes patients to aspirate food and liquid. For additional information on dementia, consult Chapter 20 of this textbook.

No single dysphagia profile exists for demented patients because of the variety of causes of the disease. However, common observations include the inability to feed self independently and to remain focused for the duration of the meal. Some patients do not engage in the task of eating and swallowing. They may hold food in their mouth for prolonged periods without mastication or bolus formation, especially with uniformly textured foods such as pureed items or bland foods. As a result of sensory impairments and lack of attention, the patient may fail to control the bolus in the mouth and lose it prematurely over the tongue base and into the larynx before the pharyngeal swallow has been elicited, resulting in aspiration. Moreover, their distractible or agitated behavior may prolong the feeding time and hence reduce the amount of nutrition and hydration received. Malnutrition and dehydration can produce medical complications that in turn exacerbate the cognitive decline even further.

**Systemic Dysphagia**

The broadest category of causes of dysphagia includes inflammatory and infectious factors, which affect oral, pharyngeal, and esophageal stages of swallowing. Candida esophagitis can occur in an immunocompromised host, such as in patients with AIDS or patients who have undergone chemotherapy. Dysphagia for solids is greater than for liquids, and patients frequently complain of food getting caught. Heartburn, nausea, and vomiting are other common complaints.

Autoimmune inflammatory disorders can affect swallowing in either specific organs or the immune system as a whole. This category of diseases includes polymyositis, scleroderma, and secondary autoimmune diseases. Patients with HIV/AIDS have been shown to have aspiration on videofluoroscopy. Sometimes intrinsic obstruction is observed, such as in Wegener’s granulomatosis. With other disorders, there is external compression, abnormal esophageal motility as in scleroderma, or inadequate lubrication as in Sjögren’s syndrome. Pharyngeal and esophageal symptoms are common. Poor esophageal motility restricts patients to small meals of pureed or liquid substances, and eating duration is long and drawn out. Patients report the sensation of solid foods getting caught in the esophagus. Weight loss is frequent. Gastroesophageal reflux results from poor esophageal peristalsis.

**General Deconditioning**

Multisystem diseases, including the more frequently encountered progressive diseases such as end-stage chronic obstructive pulmonary disease, coronary artery disease, and chronic
renal failure, cause insidious weakness. Weight loss in these patients is a common consequence because of reduced endurance for activities of daily living, including eating and swallowing. Patients with emphysema have difficulty coordinating swallowing and respiration, and may be unable to tolerate the obligatory cessation of breathing required for airway protection during the swallow. General immobility impairs spontaneous pulmonary clearance, resulting in an inability to expectorate material if it is aspirated. Patients are often discouraged and depressed by their loss of independence and declining health.

Medications can play a major role in causing dysphagia. The number of medications increases proportionally to the number of disorders to be treated, but their reactions may be exponential. Medications can affect lubrication of the oral cavity and pharynx, reduce coordination or motor function, and cause local mucosal toxicity. This is discussed further under xerostomia. Antipsychotic or neuroleptic medications can produce extrapyramidal motor disturbances, resulting in impaired function of the striated musculature of the oral cavity, pharynx, and esophagus. Long-term use of antipsychotics may result in tardive dyskinesia, with choreiform tongue movements affecting the coordination of swallowing. Delayed swallow initiation is a reported side effect of some neuroleptic medications.

Assessment

Approaching the evaluation of swallowing in the terminally ill patient demands a holistic view and reaches beyond the physiology of deglutition. While aspiration of food or liquid could realistically evolve into aspiration pneumonia, paradoxically, committing a patient to nonoral feeding or non per os (NPO) is also fraught with complications. It therefore behooves caregivers to carefully consider the multiple parameters in decision-making about oral nutrition in the terminally ill patient. The matter is not a simple decision of “if the patient is aspirating he or she should not receive nutrition orally.”

For the patient with a life-threatening illness, the goals of the clinical swallowing evaluation are to (1) identify the underlying physiological nature of the disorder; (2) determine whether any short-range interventions can alleviate the dysphagia; and (3) collaborate with the patient, family, and caregivers on the safest and most efficacious method of nutrition and hydration.

Evaluation of dysphagia in patients receiving palliative care is best accomplished within a multidisciplinary framework where the patient’s needs and wishes are held paramount. The patient may report coughing or choking sensations while eating or drinking. A number of patients underestimate their swallowing difficulty, having accommodated to the gradually increasing dysphagia. Nurses and family caregivers usually report symptoms of difficulty swallowing when the problems are witnessed regularly at meals and while administering medications. In some cases, there may be no overt coughing spells when the patient is eating or drinking, and the question of aspiration is entertained because of recurrent pneumonias. Speech language pathologists who are skilled at identifying causes of oropharyngeal swallowing and who understand the complications of dysphagia can be consulted to evaluate the swallowing behavior and to suggest compensatory management strategies for alleviating the dysphagia. In terminally ill patients, it may be possible to determine the least restrictive diet that will provide the patient with safe and efficient oral intake while at the same time preserving a small amount of pleasure associated with eating by mouth. The assistance of a gastroenterologist may be required in cases requiring palliative dilation of the esophagus.

Clinical History

A comprehensive understanding of the difficulties involved in swallowing depends in large part on a detailed history from the patient and caregivers. Eliciting a description of the patient’s complaints about swallowing is critical to painting a picture of the physiological basis of the problem and to integrating these hypotheses with attitudes and wishes about eating and not eating. Details of disease progression along with the accompanying emotional and psychological impact on the patient and the family should also be considered when determining the aggressiveness of a swallowing work-up and its treatment.

The swallowing history may indicate a mechanical obstruction etiology or an underlying neuromuscular cause. Asking the patient which foods are easier and which are avoided, with special focus on liquids versus solids, provides clues about the location of the disorder. For example, patients who complain of solid food dysphagia and localize the area of difficulty to the throat may present with bolus propulsion problems, whereas those who choke on liquids may have a sensory deficit with mistiming of airway protection. It is important to note low diagnostic specificity regarding the patient’s localization of the problem with radiographic or endoscopic findings.

Information about the patient’s current eating habits and diet should be elicited. Does the patient choke on all consistencies of solid foods and fluids? Can the patient feed himself or herself? How have meal times changed since the illness? What is the total calorie intake the patient receives on a daily basis, and how far short does this fall from the patient’s nutritional requirements? Length of meal times and effort required are indicators of eating efficiency. Additional areas of concern include appetite, factors that appear to alleviate or exacerbate the problem such as positioning, time of day, ability to swallow medication, and the presence of pain on swallowing.

The current complaints with respect to the physiology of swallowing are as important as the patient’s previous attitudes toward eating. These attitudes form the foundation on which management strategies are implemented. The patient with a poor appetite, fatigue, and a sense of hopelessness will understandably be less compliant and less motivated to engage in
a complex treatment program. Additionally, the patient and caregivers should understand and consider the competing benefits and risks regarding nutrition, with attention to the patient’s preferences.

Table 10–1 lists frequently encountered complaints by patients regarding swallowing and their potential physiological counterparts.

### Examination of Swallowing by Direct Observation

Direct observation by a perceptive clinician of the patient while eating, drinking, or taking medications can yield valuable information about the underlying disorder. As discussed previously, the speech-language pathologist is vigilant for indications of chewing inefficiencies, aspiration, or obstruction. Table 10–2 lists warning signs that can alert caregivers to possible swallowing problems.

Usually, the clinician assesses the patient’s oral motor sensory function and cognitive communicative function, while observing the partaking of a variety of liquid and solid foods (e.g., semisolid, soft solid, and, where appropriate, food requiring mastication). Speech and voice are analyzed, (bearing in mind the piston–chamber model described earlier) to determine the underlying physiology of the swallowing disorder. Since aspiration may be silent in up to 40% of patients with dysphagia, close attention is paid to occult signs of aspiration, including wet vocal quality or gurgliness, frequent throat clearing, delayed coughing, and oral/pharyngeal residue.

### Assessment of Oral Hygiene

The status of the oral mucosa and general oral hygiene reflect a patient’s ability to manage secretions and swallowing. As mentioned earlier, xerostomia may exacerbate, and in some cases even cause, difficulty swallowing. Patients who require supplemental oxygen delivered via a nasal cannula frequently experience dryness in the oral cavity. It is not uncommon to find dry secretions crusted along the tongue, palate, and pharynx in patients who have not eaten orally in some time. Dental caries and dentures that are not well cared for can also contribute to a state of poor oral hygiene as well as poor quality of life. Before giving the patient food or liquids, even for assessment purposes, it is vital to clear the oral cavity of extraneous secretions, using mouth swabs, tongue scrapers, toothbrushes, and oral suction if necessary. Dried oral secretions may loosen during trials of fluid and inadvertently obstruct the airway.

### Evaluation of the Gag Reflex

A word of caution is needed regarding the gag reflex and oropharyngeal swallowing. Health care professionals routinely assess the gag reflex as a predictor of swallowing behavior. The gag reflex and the pattern of neuromuscular events comprising the swallow are very different, both in their innervation and in their execution. The gag reflex is a protective reflex that prevents noxious substances arising from the oral cavity or digestive tract from entering the airway. It involves simultaneous constriction of the pharyngeal and laryngeal muscles closing the airway and the pharyngeal lumen and results in anterior movement of the tongue. A gag reflex is not elicited during the normal swallow. Unlike the pattern of events in the swallow, the gag reflex can be extinguished or reduced by a nasogastric feeding tube, endotracheal intubation, or repeated stimulation. The pharyngeal swallow response, which closes the airway and opens the

Dysphagia, Xerostomia, and Hiccups 203
upper esophagus, cannot be extinguished once it begins, and it continues in a predetermined progression until the sequence of events is completed. These inherent differences highlight the need to examine the gag reflex and the swallow separately. Only evaluation of the biomechanical events of the swallow, not the gag reflex, can predict the safety of airway protection.

**Assessment of Airway Protection.** Functional airway protection is a critical predictor of safe swallowing and, thus, an important element of the clinical swallowing evaluation. Effective airway protection entails timely and complete laryngeal closure during swallowing and the efficient expectoration of material in response to aspiration. Audible strong cough at the glottis and pharyngeal contraction, which is necessary for bringing up a sputum sample, are required for functional airway protection. Patients who have weak voices and weak respiratory force for coughing and pulmonary clearance are at risk for pulmonary compromise. Airway protection cannot be definitively discerned from a clinical evaluation alone. Although the clinician may palpate moderate superior and anterior laryngeal elevation on swallowing, may perceive a normal vocal quality, and may not observe cough on swallowing, the patient may in fact be silently aspirating. Silent aspiration can only be confirmed definitively with an instrumental examination. Previous radiation therapy, as well as cranial nerve IX (glossopharyngeal) and X (vagus) deficits, may all contribute to the picture of silent aspiration. Depending on the stage of progression of the patient’s illness and overall management goals, it may be prudent to identify silent aspiration with the aim of limiting progression with behavioral strategies.

**Instrumental Evaluation**

The clinical examination of swallowing is not conclusive regarding location of the swallowing disorder or the underlying physiology. Radiographic or endoscopic evaluation of swallowing are functional examinations providing valuable information for management. Sometimes disease progression with its sequelae, including inability to travel, inability to sit upright, wakefulness, pain and/or somnolence, preclude instrumental examination. Management shifts from maintenance to comfort, with compensatory behaviors being inappropriate.

**Videofluorographic Evaluation of Swallowing.** Radiographic swallowing studies are helpful in understanding the underlying physiology of swallowing.2 The videofluorographic swallowing study (commonly known as modified barium swallow study) examines oropharyngeal swallowing with the patient positioned upright while swallowing a variety of consistencies of barium-coated foods (liquids, semisolids, and solids) in controlled volumes. Speech pathologists and radiologists perform these studies together. The goal of this study is not only to determine the presence or absence of aspiration but also to evaluate the effectiveness of compensatory swallowing strategies (described below) that may decrease the risk of aspiration and increase swallowing efficiency. The test is not invasive, takes a short time to administer, and provides valuable information that can be used in managing the dysphagia.2,38

assessed.\textsuperscript{16} Since the esophagus is under involuntary neural control, compensatory swallowing strategies cannot be assessed with this procedure. However, recommendations can be made for changing to liquid consistencies in a patient with an esophageal stricture.

Endoscopic examination of oropharyngeal swallowing can be performed at the bedside by a trained speech-language pathologist. The oropharynx and larynx can be visualized transnasally while the patient is swallowing food substances dyed with food coloring and the presence of laryngeal penetration, aspiration, and pharyngeal retention can be observed. As in the videofluoroscopic swallowing study, compensatory swallowing strategies such as postural modifications or swallowing maneuvers can be evaluated for their efficacy.\textsuperscript{39} Endoscopic evaluation of the esophagus and stomach while the patient is sedated can confirm the presence of strictures and mucosal anomalies.\textsuperscript{16}

**Assessment of Compensatory Swallowing Strategies**

The physiologic information obtained from the clinical and instrumental swallowing facilitates on-line assessment of intervention strategies aimed at increasing swallowing safety and efficiency. These include alterations in head and neck posture, consistency of food, sensory awareness, and feeding behaviors. The chief advantage of these strategies is that they are simple for the patient to learn and to perform. In addition, once their effectiveness is determined, the patient can use the intervention during meals to improve swallowing function.

**Postural Modifications.** Postural changes during swallowing often have the effect of diverting the food or liquid to prevent aspiration or obstruction but do not change the swallowing physiology.\textsuperscript{2,38} A commonly used strategy is the chin tuck posture. This posture has the advantage of increasing the pressure on the bolus and restricting the opening of the laryngeal inlet during swallowing, thus potentially reducing the risk of laryngeal penetration and aspiration. However, in select cases a chin tuck may exacerbate the aspiration, underscoring the need for radiographic evidence of its clinical value, if at all possible. Head rotation to the weak side in a patient with head and neck cancer is another postural change that may assist bolus flow down the intact side by obstructing the weak side and, hence, preventing residue or aspiration. These strategies may be used in isolation or in combination depending on the nature of the underlying swallowing pathophysiology.

Although it is not possible to detect the effectiveness of these strategies with complete certainty at the bedside, they may have empiric benefit that could be tested with an instrumental procedure, if that is deemed appropriate or necessary in the future. Table 10-3 lists some of the postural strategies that may be introduced and their potential benefits on bolus flow.

**Changes in Texture and Consistency of Food.** Underlying physiological constraints, such as reduced tongue control or strength, may affect the safety of swallowing certain solids or liquids. The patient with advanced ALS or Parkinson’s disease with profound tongue weakness may exhibit signs of aspiration on thin liquids but may have sufficient control to drink liquids thickened to a nectar-like or honey-like consistency in small sips. Patients debilitated by chronic disease and who lack endurance to complete a meal may benefit from ground or pureed moist foods that require limited mastication. In certain circumstances, altered food consistency is the only way a patient

can continue to eat orally, for example, in the patient with esophageal carcinoma or a severe esophageal motility disorder. Some nutritional supplement drinks are both thicker liquids and calorically fortified, providing a safer alternative to more solid consistencies.

Changes in the consistency of food and liquid are frequently difficult for patients because they often lack appeal. Thus, this management strategy should be used as a last resort and reserved for patients who are unable to follow directions to use postural changes or for whom other compensatory strategies are not feasible.2

**Increased Sensory Awareness.** Sensory enhancement techniques include increasing downward pressure of a spoon against the tongue when presenting food in the mouth and presenting a sour bolus, a cold bolus, a bolus requiring chewing, or a large-volume bolus. These techniques may elicit a quicker pharyngeal swallow response while reducing the risk of aspiration. Some patients benefit from receiving food or liquid at a slower rate, while others are more efficient with larger boluses. Enhancing the bolus characteristics to include more texture can sometimes induce mastication and bolus formation more readily than a bolus that is both flavorless and homogenous in texture. This is particularly evident in patients with advanced dementia. Patient responses to these behaviors can be evaluated at the bedside, and the findings can be easily communicated to the caregivers.2

**Secondary Behaviors.** Attention is focused on the secondary behaviors that have an impact on the efficiency of swallowing. For example, the patient’s attitude toward eating, endurance, efficiency of swallowing, and the length of time it takes to eat a meal influence the overall nutritional picture and, ultimately, quality of life.

**Management**

Effortless, efficient, and safe swallowing are important criteria for continued oral nutrition. Experience has shown that most patients prefer oral alimentation even if it means they do not receive sufficient nutrition. Patient autonomy in shared decision-making is a critical ethical principle to respect but should be accompanied by a clear understanding of the risks involved in eating by mouth. Specifically, families and patients should be informed about the risks and consequences of developing aspiration pneumonia and malnutrition. Health care professionals must present the information in as objective a manner as possible, taking the patient’s wishes or the wishes of the surrogate decision-maker into consideration. If the decision is to continue with oral intake, the safest diet should be suggested and aspiration precautions introduced, using assessment of the swallowing problem as a guide.

The decision to pursue the option of nonoral nutritional support has significant ramifications for both the patient and the family. The family may feel that they have neglected their obligation to nourish their loved one safely and may be overwhelmed by the practical obligations demanded by the nonoral route, for example, frequent nocturnal feedings, monitoring of gastric residuals, etc. However, tube feeding may provide the patient with several more months of improved quality of life afforded by strength and endurance. Patients and families may also feel a sense of reduced pressure to eat by mouth because of the tube feeding.

**Pharmacological Management.** There are no pharmacological agents that directly act on swallowing function. However, there are agents for concurrent issues, which can exacerbate an underlying mucosal problem.

Candida esophagitis requires oral antifungal agents such as nystatin topical every 4 hours for 2 to 3 weeks.40 Other antifungal medications include ketoconazole, miconazole, fluconazole, and amphotericin B. Immunocompromised patients with candidiasis require potent systemic antifungal medications. Resistance can occur, however, in patients with long-term prophylaxis. Patients who fail the above regimen may be considered for antiviral agents.41 The prokinetic agent or ranti-tidine may be prescribed for poor esophageal motility, and proton pump inhibitors have been found to be effective in patients with gastroesophageal reflux disease.42

**Dietary Changes.** Evaluation results highlight the most appropriate nutritional method for the patient. If oral alimentation has been determined as safe, the guiding principle for diet is to ingest the maximum amount of calories for the least amount of effort. Examples of modified diets are listed in Table 10–4.

Nutritionists can provide individualized suggestions for calorie-dense foods or high-calorie liquid supplements, depending on the patient’s metabolic status. Patients with oropharyngeal dysphagia may require thickened liquids. Commercial thickening agents from modified food starch can be used to thicken liquids. These release the fluid in the gastrointestinal tract and provide water for hydration requirements.43

**Feeding the Patient.** While there is no cure for a swallowing disorder in the terminally ill patient, continued ability to eat by mouth may be facilitated by careful hand-feeding techniques and strategies employed by family and caregivers. These techniques will vary depending on the underlying swallowing/feeding difficulty. Compliance with feeding strategies is often related to understanding of the rationale. Family members are more likely to feed a patient a particular diet and in a particular manner if they understand the physiological and psychological reasons for the recommendation and if they have been included in the decision-making.2 Although hand feeding is time consuming, it allows for continued intimate contact between patient and caregiver. Interestingly, hand feeding has been shown in some cases to equal duration of survival compared with patients who have gastrostomy tubes placed.44
Additional suggestions for feeding the patient include the following:

1. Remove distractions at mealtime. This is appropriate for patients who need to concentrate on swallowing to increase safety, such as patients with head and neck cancer who are using compensatory swallowing strategies, and for patients who easily lose their focus and need to be fed, such as patients with Alzheimer’s dementia.

2. Emphasize heightened awareness of sensory clues, such as feeding patients larger boluses, increasing downward pressure of the spoon on the tongue to alert the patient that food is in the mouth, or feeding patients cold or sour boluses or foods requiring some mastication. Some patients with Alzheimer’s disease demonstrate the most efficient swallow when offered finger foods that require chewing. These foods allow them to tap into the automatic motor rhythm of chewing and swallowing that is reminiscent of the patterns they have used all their life.

3. Provide feeding utensils. Patients with multiple sclerosis who have feeding difficulties associated with hand tremors may be aided with devices such as weighted cuffs that reduce the intention tremor. These may also be useful in patients with Parkinson’s disease. Occupational therapists are often able to provide individualized assistive devices to patients.

4. Position the patient. Ensure optimal posture of the patient at meals, that is, reduce the tendency to slump forward, causing loss of food from the oral cavity, or head extension, making the airway vulnerable to aspiration.

5. Schedule meal times. Some medications enhance swallowing function. For example, patients with Parkinson’s disease may become more alert and flexible after their medications. Thus, timing of meals to coincide with increased function may enhance swallowing efficiency and safety. In contrast, some medications, particularly benzodiazepines such as valium, may increase somnolence and produce bradykinesia, affecting the efficiency of swallowing. In such cases, withholding oral intake may reduce the risk of aspiration.

**Nonoral Nutrition.** Some patients require primary nonoral feeding, and gastrostomy or jejunostomy tubes are placed endoscopically or in open surgical procedures. Some patients, such as those with esophageal cancer, head and neck cancer, or ALS, have had their feeding tubes in place for several months prior to the terminal period. For other patients, families and caregivers may have recently decided to pursue the nonoral feeding option. Irrespective of the scenario, the following should be considered:

1. The presence of a feeding tube does not imply NPO, or nothing by mouth. Some patients are able to take small amounts of food for their pleasure. Restrictions to reduce the risk of aspiration may apply during these “trials” of oral intake, such as texture of the food, postural requirements, and length of the trial.

2. Patients who are fed nonorally remain at risk for aspiration of either oral secretions or refluxed gastric contents, including tube feeding and aspiration pneumonia. A long-term study by Langmore and associates examined the predictors of aspiration pneumonia in 189 elderly patients, including such factors as oropharyngeal and esophageal dysphagia, medical and dental status, feeding status, and functional status. They found that the dominant risk factor for aspiration pneumonia was dependence.
for feeding, that is, inability to feed oneself. This variable included those patients who were tube-fed as well as those who were fed orally by a caretaker. This study found that patients who were tube-fed had a significantly increased risk of developing aspiration pneumonia. The authors posited that oral hygiene is frequently neglected in tube-fed patients, promoting colonization of bacteria, and aspiration of these secretions can result in pneumonia.

3. Inserting a form of nonoral nutrition in a patient with a terminal illness is controversial and is the subject of numerous recent publications, particularly in relation to institutionalized adults with advanced cognitive impairment due to dementia. Continued careful hand feeding over artificial nutrition is the overwhelming recommendation by the geriatricians who have conducted studies comparing multiple outcome parameters including survival, cost, and quality-of-life ratings.46

Gastroesophageal Reflux Precautions. Poor esophageal motility or reduced tone of the lower esophageal sphincter can be managed either pharmacologically with the pro-motility agents described above or nonpharmacologically. Ideally, a combination approach is most efficacious. Gastroesophageal reflux precautions include elevation of the head of the bed to 45 degrees at night, inexpensively and effectively accomplished by placing blocks under the head of the bed; frequent small meals; upright posture for 45 to 60 minutes after eating; monitoring of gastric residuals in tube-fed patients, and avoidance of spicy foods, coffee, tea, chocolate, and alcohol.47

Administration of Medication. Oral medications can present enormous challenges to patients with dysphagia. Patients who take pills with fluid complain that they can swallow the water but the pills get caught in the throat. This phenomenon is explained by the differences in speed of transit of the fluid and the pill: the water travels more rapidly than the pill. Patients with delayed pharyngeal swallow initiation, reduced tongue strength, and/or pharyngeal contractions are unable to coordinate propulsion of the entire bolus. Crushed medications or burying them whole in a semisolid such as applesauce or ice cream creates a similar consistency and makes swallowing easier. Alternately patients can be offered their medications in elixir form. A recent development is a new technology that packages the widely used compounds used in medications into tablets that disintegrate and dissolve on the tongue (RaptiTab Technology, Schwarz-Pharma, Milwaukee WI). This type of medication delivery would be most helpful for the dysphagic patient having difficulty swallowing tablets.

Tracheostomy Tubes and Oral Intake. The presence of a tracheostomy tube does not preclude oral intake. In fact, access to the upper respiratory tract improves pulmonary toilet in patients who have chosen to eat in spite of aspiration. Contrary to common thinking, an inflated tracheotomy cuff is not fully protective against aspiration.2,47 The seal in the trachea is not complete, and material sitting above the cuff can be aspirated. Tracheal suctioning should be performed after meals in patients with dysphagia who have chosen to eat. Ideally, the cuff should be deflated and the patient encouraged to cough, clearing material that may have been aspirated.

**DRY MOUTH (XEROSTOMIA)**

**CASE STUDY**

**Mrs. M, a Patient with Abdominal Pain**

Mrs. M was an 80-year-old woman with a history of dementia, end-stage cardiac disease, and peripheral vascular disease. One weekend she developed abdominal pain and was admitted to the hospital. Work-up revealed a blockage with probable toxic colon. She was made NPO and placed on multiple antibiotics to prevent further infection. She became more agitated and was given round-the-clock haloperidol. She was started on an IV morphine drip. However, she complained of constant thirst. The nurses provided her with frequent mouth swabs. They also painted artificial saliva in her mouth and applied lip balm to her lips. They brushed her teeth several times a day to stimulate saliva.

**Definition**

Xerostomia is the sensation of oral dryness, which may or may not be accompanied by decreased salivary secretions. Although patients receiving palliative care commonly experience oral dryness, it may be difficult to identify the exact underlying cause and contributing factors. Decreased salivary function and prolonged xerostomia cause myriad oral/esophageal problems in the mouth, including dental caries, gum, tongue, and oral mucosal irritations and lesions, mouth infections, taste changes, bad breath, swallowing problems, and speech problems. Thus, treatment offers much comfort to patients by moisturizing dry lips and mouth, but also by eliminating these long-term sequelae. Ultimately, sleep, rest, and nutrition are secondary issues arising out of these problems.50,51

**Incidence**

Due to lack of studies outside of the cancer population, it is difficult to estimate the incidence of xerostomia. In a prevalence study of palliative care admissions, 55% experienced xerostomia.52 Other authors estimate that xerostomia affects
Xerostomia results from four causes. First, it may result from reduced salivary secretion. Common causes include surgery performed on head and neck areas, radiation aimed at head and neck regions, medication side effects, infections, hypothyroidism, autoimmune processes, and sarcoidosis. Second, xerostomia may be caused by buccal erosion. Potential factors are cancer and cancer treatment, particularly chemotherapy and radiation. Additionally, immunocompromised conditions such as AIDS, arthritis, or lupus may exacerbate dry mouth. Third, local or systemic dehydration may induce xerostomia. Factors contributing to dehydration include anorexia, vomiting, diarrhea, fever, drying oxygen therapies, mouth breathing, polyuria, diabetes, hemorrhage, and swallowing difficulties. Fourth, other miscellaneous disorders such as mental health issues including depression, coping reactions, anxiety, and pain can cause xerostomia.46–50 There has been a long-standing assumption that as one ages, dry mouth naturally occurs as part of the process. In fact, age is not a factor;50,51 rather, as one ages, the chance of dry mouth increases due to increasing comorbid conditions that occur in the older adult, along with the higher probability of the necessity to take more medications.50

Although saliva is necessary for oral nutrition, it also facilitates chewing, swallowing, tasting, and talking. For these functions, its properties allow lubrication, repair, food-bolus formation, and food breakdown. Additionally, saliva breaks down bacterial substances, offering immunoprotection for oral mucosa and dental structures.50,51 In this way, it has antimicrobial properties, buffering properties, and liquid properties to help with gustation. Saliva thereby inhibits dental caries and infections, while providing protection against extreme temperatures of food and drink.50,51,55–57

The function of saliva production is regulated by the nervous system. After experiencing smell, sight, or taste of food, the salivary glands are stimulated to produce saliva within 2 to 3 seconds.57 There is a two-step process to saliva secretion; production at the acinar level of the cells, and secretion where saliva is actually secreted into the mouth via the ducts.50 Saliva is comprised of several elements. Ninety-nine percent of saliva is fluid composed of water and mucus, providing a lubricative element. The remaining 1% of saliva is solid, containing salts, proteins, minerals such as calcium bicarbonate ions, and enzymes such as pyalin, antibodies, and other antimicrobial agents.48–51,55

Saliva is produced by numerous glands in the oropharynx,50,55 where the average healthy adult produces up to 1.5 liters of saliva a day. The parotid glands, the submandibular glands, and the sublingual glands produce 90% of saliva, with the rest produced in the oral pharynx. Parotid glands, located below and in front of each ear, produce a serous and watery saliva.57 Therefore, damage to the parotid gland will produce a thicker saliva. Submandibular glands, located in the lower jaw, secrete mostly serous saliva with some mucinous elements.57 Sublingual glands produce purely mucous saliva.55,58 The overall viscosity of saliva is dependent on the functioning of the various glands.

There are numerous causes of xerostomia. Medications are notorious culprits of dry mouth, particularly several categories commonly used in palliative care.50,58 These medications include sedatives, tranquilizers, antihistamines, antiparkinsonian medications, antiseizure medications, skeletal muscle relaxants, cytotoxic agents, tricyclic antidepressants, and anticholinergics. Oral dryness may result from oral diseases such as acute and chronic parotitis, or partial or complete salivary obstruction. Other diseases such as Sjögren’s syndrome, diabetes mellitus, HIV/AIDS, scleredema, sarcoidosis, lupus, Alzheimer’s disease, and graft versus host disease can cause dry mouth.50,58 Radiation to the head and neck can produce a 50% to 60% reduction of saliva within the 1st week of treatment because of inflammation.58 Chemotherapy may also cause dry mouth, particularly in advanced disease.58 Usually, dry mouth sensations are worse at night. Salivary secretions may be further reduced due to the duration of radiation and/or greater radiation doses.58,59 However, it eventually may become a more persistent issue the longer radiation continues or as disease progresses.54

Assessment

Xerostomia may be accompanied by discomfort of the oral mucosa and the tongue, such as burning, smarting, and soreness with or without the presence of ulcers. Additionally, there may be difficulty with mastication, swallowing, and speech. Taste alterations, difficulty with dentures, and an increase in dental caries may also be associated with xerostomia. Additionally, sleep may be altered because of dry mouth. Therefore, a thorough history should review these problem areas along with the subjective distress of xerostomia (Table 10–5). Reviewing onset of oral dryness correlation with medication initiation may be insightful in assessment.58

An oral exam will reveal clear indications of dry mucosa. Extraoral examination is noted for dry, cracked lips, often with angular cheilitis or candida at the corners of the mouth.50 Extraoral examination includes inspection of both mucosal and buccal dryness, noting whether the mouth is pale and dry, the presence of a dry and fissured tongue, the absence of salivary pooling, and the presence of oral ulcerations, gingivitis, or candidiasis.49,55 Finally, salivary glands should be noted for swelling, indicating obstruction, and dentition should be examined for caries.50
Two quick bedside tests are the cracker biscuit test and the tongue blade test. The cracker biscuit test involves giving a patient a dry cracker or biscuit. If the patient cannot eat the cracker without extra fluids, xerostomia is present.49 The tongue blade test is an extension of mouth inspection. After inspection is complete, the tongue blade is placed on the tongue. Since dry mouth makes a ropey, pasty saliva, the tongue blade will stick to the tongue of a patient with xerostomia.55

Another, more aggressive test is unstimulated or stimulated sialometric measurement of saliva. This test measures the amount of saliva collected by spitting into a container, swabbing the mouth with a cotton-tipped applicator, or salivating into a test container at a set time.49,55 However, for most palliative care patients, this may be a burdensome and unnecessary test.

To document the extent of xerostomia, it may be helpful to use rating scales specifically designed for this purpose. Two scales, contained in Table 10–6, rates xerostomia in a four-point system.60,61

### Management

Much of xerostomia management focuses on interventions to alleviate rather than interventions to eradicate or to prevent the symptom. This is because there is little to offer patients to ward off oral dryness. Therefore, the goal becomes protecting patients from further complications, which may be more problematic.62 Medical treatment of xerostomia, as summarized in Table 10–7, would involve the following stepwise approach:

1. Treat underlying infection or disease. Candidiasis can cause xerostomia. Treating it with nystatin swish-and-swallow or with fluconazole 150 mg PO can improve xerostomia.48,50,54,55
2. Review and alter current medications as appropriate. There are some 500 medications that may cause oral dryness as a side effect.50,58 Specifically, anticholinergics, antihistamines, phenothiazines, antidepressants, opioids, β-blockers, diuretics, anticonvulsants, sedatives, and tobacco all may cause oral dryness. Thus, patients with heart conditions, mental health issues, depression, anxiety, neurological disorders, and pain disorders may be at risk for dry mouth. It is important to first evaluate the necessity of specific xerostomia-inducing drugs. If eliminating possible culprits is not possible, other possible strategies include decreasing the dosage to decrease dryness, or altering the schedule to assure that the peak effect of medication does not coincide with nighttime peak of decreased salivary production.48–50,55
3. Stimulate salivary flow. Salivary stimulation can occur with both nonpharmacological and pharmacological interventions.
4. Replace lost secretions with saliva substitutes.

Nonpharmacological Interventions

Nonpharmacological use of gustatory stimulation includes simple measures. Table 10–8 summarizes possible procedures. All of these interventions, except acupuncture, are inexpensive and may be as efficacious as medications for some patients, without uncomfortable side effects. However, relief is not long-lasting.55

- **Peppermint water.** Peppermint stimulates saliva and can be taken as needed. However, it should not be used with metoclopramide as they have opposing actions.48–50
- **Vitamin C.** Use in lozenges or other forms as preferred. Disrupts salivary mucins to reduce viscosity of saliva.56 Although inexpensive, vitamin C may be irritating to the mouth, particularly if the patient has mouth sores.54 Also, there is a need to be careful as continual vitamin C can erode dental enamel.56
- **Citric acids.** Present in malic acid or in sweets. Citric acids can act similar to vitamin C in causing a burning sensation.54
- **Chewing gum, mints.** Preferably sugarless, to prevent caries and infections, as an immunocompromised state can hasten cavities and infections. These are most preferred by patients, are cheap, and have no side effects. May create a buffer system to compensate for dietary acids.54,56
- **Acupuncture.** Effective with a variety of types of xerostomia, although mechanism not understood. It occurs as a single treatment with eight needles placed in three places: bilaterally in the ears and a single distal point in the radial aspect of the index finger.57 One study showed that 6 weeks of twice-weekly treatment increased salivation for up to 1 year.63 Another study used a 3-to-4 weekly regimen, with monthly maintenance visits to relieve xerostomia.54

Pharmacological Interventions

- **Pilocarpine.** Pilocarpine is a parasympathetic agent that increases exocrine gland secretion and stimulates residual functioning tissue in damaged salivary gland. Saliva production is greatest after a dose and response lasts for about 4 hours.56 Dose is 5 mg PO tid or QI, not to exceed 10 mg per dose.57 Response varies with severity of xerostomia. Side effects include mild to moderate sweating, visual disturbances, nausea, rhinitis, chills, flushing, dizziness, abdominal cramping, and asthenia,54,55,57 but can be lessened if taken with milk.56 Pilocarpine should not be used in patients with chronic obstructive pulmonary disease or bowel obstruction.54,55,57 New studies have shown that pilocarpine given before and during radiotherapy can reduce xerostomia.54,65,66
- **Bethanechol.** Bethanechol relieves anticholinergic side effects of tricyclic antidepressants. Few studies

have been done that focus specifically on xerostomia rather than the side effects of antidepressants.8,43,55

- Methacholine. Methacholine is a parasympathomimetic compound that increases salivation. Dose is 10 mg a day. One side effect is hypotension. It is short-acting.54,55

- Yohimbine. Yohimbine blocks α2-adrenoreceptors. Side effects include drowsiness, confusion, and atrial fibrillation, lasting up to 3 hours. Dose is 1.4 mg a day.54,66

- Cevimeline. Cevimeline is a muscarinic agonist that acts to increase saliva by inhibiting acetylcholinesterase. It works on salivary glands and lacrimal glands. Used in a spray or mouthwash, it lasts up to 6 hours.56,57

- Water. Water is simple and inexpensive. It is usually well tolerated and easily accessible. There is no research on whether optimal relief results from either warm or cold. Thus, temperature is a personal choice.54,55

- Artificial saliva. Artificial saliva contains carboxymethylcellulose or mucin; dose 2 mL every 3 to 4 hours.56,57 Some examples include Glandsosane, Xero-Lube, Orex, and Saliment.51,56

- Protect teeth. Oral hygiene, such as frequent brushing with soft brushes, water jet, denture cleaning, fluoride rinses, mouthwash, and flossing, stimulate salivation. This can help prevent candidiasis, particularly since dentures can harbor infections.50

- Use of lip balm prevents cracked lips, and use of saliva moistens lips. Care should be taken not to use products with alcohol since these can be irritating.54,57,60,61

- Dentifrices. Several are manufactured for patients with dry mouth that contain antimicrobial enzymes to reduce oral infections and enhance mouth wetting. Examples are Biotene and Oral Balance.50,56,57

- Mouthwashes. Help rinse debris from mouth. Includes homemade mouthwashes made from saline, sodium bicarbonate, glycerin, and perhaps lemon.50,56

- Rehydrate. Replenish oral hydration by sipping water, spraying water, and increasing humidity in the air.67 To assist in sleep, instituting these measures at night may help rest.

- Modify diet. Education regarding the avoidance of sugars, spicy foods, sometimes salt, and dry or piquant foods is important. Patients may sip such foods in milk, tea, or water to assist in swallowing. In addition, instruct patients to take fluids with all meals and snacks. The use of gravies and juices with foods can add moisture to swallowing. Again, preferred tastes may vary from one patient to the next regarding salt, sweet, and sour. For dry mouth without oral ulcerations, provide carbonated drinks such as ginger ale, as well as cider, apple juice, or lemon-ade. Fresh fruits, papaya juice, or pineapple juice may help some patients refresh their mouths.54,66 However, citrus products may be too acidic and irritating for other patients.56

**Nursing Interventions**

Because the degree of xerostomia varies, nursing intervention will vary from one patient to the next. Little research has focused on dry mouth, and clear evidence of the efficacy of one treatment over another has not been demonstrated. The result is a lack of standardized oral care procedures, with protocol varying from one institution to the next. Therefore, the nurse must assess how much distress xerostomia is causing and help patients find a suitable therapy within their financial means.

Both the financial and physical burden of therapy may be of concern for patients. Many patients choose nonpharmacological therapy because it is inexpensive and has fewer side effects.54 Other patients may consider nonpharmacological interventions depending on how many other symptoms they are experiencing or how many other medications they are currently taking. If a pharmacological therapy is chosen, it is important to consider previous patient choice, as patients seem to prefer saliva stimulants to saliva substitutes.24 If saliva substitutes are used, those with a mucin base appear to be better tolerated than those derived from carboxymethylcellulose.68 However, both types of preparation bases are better tolerated as an oral spray than as a gel or rinse.68 The issue of prophylactic antifungal therapy occasionally arises. The evidence thus far has not shown it to be beneficial.

Patient and family education focuses on the goal of treatment as palliative. The nurse may help a family systematically go through a variety of therapies to achieve relief. Helping patient and families to demonstrate good oral care maintains the comfort of the patient. As a patient weakens, provision of mouth care gives a family member a tangible role in care.

**HICCUPS**

**CASE STUDY**

**MB, a Patient with Gastric Cancer**

MB is a 70-year-old male with rapidly progressing gastric cancer. He was diagnosed 7 months earlier and underwent chemotherapy. He is fairly weak and has begun to get more pain and discomfort. His wife cares for him at home in a small guest room because he is bedridden and has no energy to climb the stairs. His family asks the nurse to evaluate him. Upon arrival, the nurse finds him moderately uncomfortable with pain. He is disheveled, lying flat on a twin bed facing against the wall. He complains of pain in his abdomen and...
constant hiccups. He has not eaten in several days due to his discomfort. He is washed and bathed. Morphine elixir is initiated for his pain. For the hiccups, the family is encouraged to use a bolster pillow or several pillows to decrease the pressure of his large abdomen on his diaphragm and lungs. Additionally, baclofen 15 mg tid is initiated. Over the next 2 days, he is much more comfortable. After several days, his hiccups continue. The baleen is increased without effect. Because he is declining and also feeling nauseous, haloperidol 1 mg q 4 to 6 hours is initiated, which resolves the hiccups.

Definition

Hiccup, or singultus, is defined as sudden, involuntary contractions of one or both sides of the diaphragm and intercostal muscles, terminated by an abrupt closure of the glottis, producing a characteristic sound of “hic.”69–74 Hiccup frequency is usually 4 to 60 per minute.75 Prolonged hiccups can produce fatigue and exhaustion if sleep is interrupted. Additionally, anxiety, depression, and frustration may arise if the important daily activities of eating or sleeping are interrupted. The long-term effects are exhaustion, increasing distress from lack of rest, and wasting because of interference with eating. Therefore, although seemingly a mere disturbance with no long-term pathology, intractable hiccups affect the quality of life.69,71,72,75

Prevalence and Impact

Hiccups in palliative care have not been well studied. Estimates of prevalence of hiccups in cancer patients is about 10% to 20%.76 Because of their perceived insignificance, the incidence and prevalence are not well known. Additionally, most discussion of the impact of hiccups occurs in case reports. Children are more at risk than adults.76

Pathophysiology

There are three categories of hiccups. First are benign, self-limiting hiccups, which occur frequently. Such a bout of hiccups can last from several minutes to 2 days. Benign hiccups are primarily associated with gastric distention.66,77 However, sudden changes in temperature, alcohol ingestion, excess smoking, and psychogenic causes may also induce benign hiccups.69,71–73 Second are persistent, or chronic, hiccups. These continue for more than 48 hours but less than 1 month. Third and last are intractable hiccups, which persist longer than 1 month.67,69,71–73 However, for patients in palliative care, these times may not be the important issue; rather, the amplitude can cause much distress, depending on the patient’s diagnosis.73

Intractable hiccups in the third category have more than 100 different causes, varying from simple metabolic disturbances to complex structural lesions of the central nervous system or infections.67,69,71,73 Particular causes can be distilled into four conditions: structural, metabolic, inflammatory, and infectious disorders.69 Specifically, structural conditions affect or irritate the peripheral branches of the phrenic and vagus nerves, such as in abdominal or mediastinal tumors, hepatomegaly, ascites, or gastric distention, and central nervous disorders in which persistent hiccups can signal serious underlying disorders, such as thoracic aneurysm, brainstem tumors, metabolic and drug-related disorders, infectious diseases, and psychogenic disorders.73,74,79 Common causes in terminal illness include neurological disorders such stroke, brain tumors, and sepsis and metabolic imbalance; phrenic nerve irritation such as tumor compression or metastases, pericarditis, pneumonia, or pleuritis; and vagal nerve irritation such as esophagitis, gastric distention, gastritis, pancreatitis, hepatitis, and myocardial infarction.71,72 Medications such as steroids, chemotherapy, dopamine antagonists, megestrol, methyl dopa, nicotine, opioids, and muscle relaxants may also cause hiccups.76

The precise pathophysiology of hiccups is unknown, as is their physiological function. It is considered a primitive function, such as yawning or vomiting, that through evolution now serves no purpose.69,72,79 The anatomical cause of hiccups is thought to be bimodal, with association either with the phrenic or vagus nerve,75,78 or central nervous involvement, which causes misfiring.72 There is thought to be a hiccup reflex arc located in the phrenic nerves, the vagal nerves, and T6–T12 sympathetic fibers, as well as a possible hiccup center in either the respiratory center, the brain stem, or the cervical cord between C3 and C5.80 However, there is not a discrete hiccup center, such as the chemoreceptor trigger zone for nausea.75,79,77

Evidence suggests an inverse relationship between partial pressure of carbon dioxide (pCO2) and hiccups; that is, an increased pCO2 decreases the frequency of hiccups and a decreased pCO2 increases frequency of hiccups.66 Interestingly, hiccup strength or amplitude varies from patient to patient as well as among separate episodes in an individual.72 Moreover, hiccups have a minimal effect on respiration.

Assessment

Extensive work-up for hiccups in palliative care may be impractical and more uncomfortable than the hiccups themselves, while revealing little. Indeed, a recent retrospective study revealed that laboratory studies neither assisted in treatment nor helped determine what treatment would be effective.81 Nonetheless, assessment should include a subjective review of how much distress the hiccups cause the patient. For example, in a patient with an abdominal tumor, hiccups can cause
excruciating pain, whereas in the obtunded patient in renal failure, hiccups may cause no distress at all.

History may give insight into the distress of hiccups. Subjective assessment includes the history and duration of the current episode of hiccups, previous episodes, and interference with rest, eating, or daily routines. Inquiry into possible triggers of hiccups episodes may be helpful, including patterns in timing during the day or other activities proceeding the hiccups such as eating, drinking, positioning, or various procedures. In addition, a review of recent trauma, surgery, or acute illness and medication history is important to help focus on potential causes of the hiccups.69,79

Usually the presence of hiccups themselves is quite obvious. However, physical exam may not reveal the cause of the hiccups, but, rather, rules out other conditions. Oral examination may reveal signs of swelling or obstruction. Observation includes inspection of the patient’s general appearance, observing for signs of a toxic or septic process. More specifically, it includes evaluating for tenderness of the temporal artery, foreign bodies in the ear, infection of the throat, goiter in the neck, pneumonia or pericarditis of the chest, abdominal distention or ascites, and signs of stroke or delirium.69

Specific testing may be warranted to eliminate other causes. Chest x-ray may rule out pulmonary or mediastinal processes as well as phrenic/vagal irritation from peritumor edema in the abdominal area.79 In addition, blood work including a complete blood count with differential electrolytes may rule out infection as well as electrolyte imbalances and renal failure.67,69,72,73

Management

The lack of research to increase understanding on the nature of hiccups has resulted in anecdotal therapy and a lack of treatment consensus. The consequence is treatment bias based on previous success rather than a systematic, evidence-based approach. Similar to treatment of dysphagia or xerostomia, treatment for hiccups should be focused on the underlying disease. If the etiology questionably includes simple causes such as gastric distention or temperature changes, “empiric” treatment should be initiated. Both nonpharmacological and pharmacological interventions may be used.69,71–73 Therapies include physical maneuvers, medications, and various other procedures to interfere with the hiccup arc.80 Otherwise, treatment for more complex episodes of hiccups without clear etiology will focus on various pharmacological interventions.

Nonpharmacological Treatment

Nonpharmacological treatments can be divided into seven categories and are outlined in Table 10–9. First are simple respiratory maneuvers. These include breath holding, rebreathing in a bag, compression of the diaphragm, ice application in the mouth, and induction of sneeze or cough.69,71–73 Second is nasal and pharyngeal stimulation. These techniques use pressure on the nose, inhalation of a stimulant, traction of the tongue, drinking from the far side of a glass, swallowing sugar, eating a lemon wedge with bitters, eating soft bread, or soft touch to the palate with a cotton-tipped applicator.72,73,75 Third is miscellaneous vagal stimulation, which includes ocular compression, digital rectal massage, and carotid massage.
Fourth are psychiatric treatments, which focus on behavioral therapy. Fifth is gastric distention relief, which encompasses fasting, use of a nasogastric tube to decrease distention, lavage, and induction of vomiting. Sixth is phrenic nerve disruption, such as an anesthetic injection or acupuncture. Seventh are miscellaneous benign remedies, such as bilateral compression of radial arteries, peppermint water to relax the esophagus, use of distraction, or acupuncture.

### Pharmacological Treatment

Initial therapy should attempt to decrease gastric distention, which is usually the problem in 95% of cases, hasten gastric emptying, and relax the diaphragm. This includes the use of simethicone and metoclopramide. If ineffective, second-line therapy should focus on suppression of the hiccup reflex. Common pharmacological interventions, listed in Table 10-10, include the use of various classes of medications: muscle relaxants such as baclofen, midazolam, and chlorzepoxide; anticonvulsants such as gabapentin, carbamazepine, and valproate; corticosteroids such as dexamethasone and prednisone; dopamine antagonists such as haloperidol, droperidol, and chlorpromazine; calcium channel blockers/antiarrhythmics such as nifedipine, nimodipine, nefopam, phenytoin, lidocaine, quinidine; SSRI antidepressants, specifically sertraline; and various other medications such as ketamine, THC, and methylphenidate. Third-line therapy is the use of other drugs to disrupt diaphragmatic irritation or other possible causes of hiccups, which may include anesthesia and phrenic and cervical blocks.

### Nursing Interventions

Although hiccups appear to be a simple reflex, their specific mechanism of action is unclear due to myriad etiologies. Nurses are helpful in providing patients and families with a review of the nature of hiccups and their role as an annoyance rather than a pathological symptom. Thus, nursing interventions should focus on information sharing and comfort, with a goal of terminating the hiccups. The extent of aggressive treatment will depend on the degree of distress the hiccups cause on the patient’s quality of life. In particular, what effect do the hiccups have on the daily routine, most particularly on sleep and nutrition? Many patients have felt frustrated that little credence was given to their discomfort and disruption caused for intractable hiccups. Thus, the nursing role is one of advocate to promote initiation of some sort of therapy, empathetic listener, and educator. Nurses can provide patients with information on some nonpharmacological maneuvers such as respiratory maneuvers, nasal and pharyngeal stimulation, distraction, and peppermint waters. If unsuccessful, the nurse should provide education on the various classes of medications as prescribed as options. An example includes antacids to decrease gas, antiemetics to affect dopamine levels, and muscle relaxants to affect both gamma-aminobutyric acid channels and skeletal muscle. Offering support to the patient is necessary since patients respond to different medications. If one class or type of medication fails, the nurse should suggest that another class of medication be tried, until all possible medications have been used. If all of these medications fail to induce hiccup reduction or cessation, the nurse should suggest a referral to a palliative care service, a pain service, or an

anesthesia service to further explore treatment therapies. These services can review all attempts at treating hiccups and provide consideration for a nerve block or other types of infusions. However, as always, discussion with the patient should include their prognosis and the benefit and burden of any procedure. The nurse can help discuss with the patient their concerns about treatment and their desire for comfort. If hiccups become extremely burdensome and all therapies have failed, sedation may be a consideration. Again, the nurse may act as an advocate to provide the necessary information about the implications of sedation. For further discussion of palliative sedation, the reader is referred to Chapter 24.

**SUMMARY**

Dysphagia, xerostomia, and hiccups are common problems that often receive little attention. Since many health care providers consider them trivial, these symptoms are seemingly underreported and underestimated. However, nurses at the bedside, whether in a facility or at home, may be the first to realize and witness the extent to which these symptoms cause discomfort and affect a patient’s life. The mere act of a nurse listening to a patient’s distress is an acknowledgment of his or her concerns. The patient feels she or he is taken seriously, as a unique individual. Moreover, the simple act of initiating treatment to manage these symptoms may promote psychological healing in itself because the patient feels respected about his or her concerns and experiences treatment as life-affirming.

The patient’s preferences and desires form the basis of any interventions. These guide both the pharmacological and/or nonpharmacological treatment within the context of his or her definition of optimal management and goals. Having established that the patient and family is the unit of care, the family should be brought into discussions concerning decision-making. The nurse can elicit their concerns, promoting understanding and relief of anxiety and fears. Additionally, when death is imminent and aggressive treatment may not be warranted, specific discussion with the patient and family should focus on the individual circumstances that suggest comfort measures.

In summary, dysphagia, xerostomia, and hiccups are distressing symptoms that may affect nutrition, cause discomfort, and affect a person’s sense of well-being. If left untreated, patients may experience physical suffering, lose a sense of dignity, and perhaps become isolated in their distress. Because patients talk differently to physicians and nurses, nurses may often receive little attention. Since many health care providers consider them trivial, these symptoms are seemingly underreported and underestimated. However, nurses at the bedside, whether in a facility or at home, may be the first to realize and witness the extent to which these symptoms cause discomfort and affect a patient’s daily routine. Therefore, nurses play a pivotal role in addressing these symptoms and initiating holistic management, providing relief, enhancing a patient’s self-opinion, improving functional status, and promoting quality of life.

Bowel Management: Constipation, Diarrhea, Obstruction, and Ascites

I feel like I am going to pop! This constipation is worse than the pain.—B. H., 58-year-old with pancreatic cancer

Key Points
- Multiple factors contribute to constipation. Proactive management is essential for successful outcomes.
- Treating diarrhea requires a thorough assessment and therapy directed at the specific cause.
- Palliative care should allow for a thoughtful and realistic approach to management of symptoms within the goals of care.

Definitions
Constipation is subjective to many patients, making assessment much more difficult. Constipation is defined as “a decrease in the frequency of passage of formed stools and characterized by stools that are hard and small and difficult to expel.” Understanding the normal functioning of the bowel can provide insight into the contributing factors leading to constipation, diarrhea, and obstruction. Associated symptoms of constipation vary but may include excessive straining, a feeling of fullness or pressure in the rectum, the sensation of incomplete emptying, abdominal distention, and cramps. The subjective experience of constipation may vary for different individuals, underscoring the importance of individualized patient assessment and management.

Prevalence and Impact
Prevalence among cancer patients is common. The impact of constipation on quality of life is substantial. Constipation causes social, psychological, and physical distress for patients, which additionally impacts the caregiver and health care staff. Failure to anticipate and manage constipation in a proactive way significantly affects the difficulty a patient will experience in attempting to relieve this problem.

Constipation affects 2% to 10% of the general population, but the incidence may be as high as 20% to 50% in older or ill persons. Constipation is a major problem in cancer patients, with as many as 70% to 100% of cancer patients having this distressing symptom. The use of opioids for pain is a contributory factor to constipation, and this side effect is the principal reason for their discontinuation. Constipation is common and yet undertreated by both physicians and nurses.
Pathophysiology

Normal bowel function includes three areas of control: small intestinal motility, colon motility, and defecation. Small-intestinal activity is primarily the mixing of contents by bursts of propagated motor activity that are associated with increased gastric, pancreatic, and biliary secretion. This motor activity occurs every 90 to 120 minutes but is altered when food is ingested. Contents are mixed to allow for digestion and absorption of nutrients. When the stomach has emptied, the small intestine returns to regular propagated motor activity.1

The colon propels contents forward through peristaltic movements. The colon movement is much slower than that of the small intestine. Contents may remain in the colon for up to 2 to 3 days, whereas small-intestinal transit is 1 to 2 hours. Motor activity in the large intestine occurs approximately six times per day, usually grouped in two peak bursts. The first is triggered by awakening and breakfast, and a smaller burst is triggered by the afternoon meal. Contractions are stimulated by ingestion of food, psychogenic factors, and somatic activity. Sykes8 found that 50% of the constipated patients in a hospice setting had a transit time between 4 and 12 days.

The physiology of defecation involves coordinated interaction between the involuntary internal anal sphincter and the voluntary external anal sphincter. The residual intestinal contents distend the rectum and initiate expulsion. The longitudinal muscle of the rectum contracts, and with the voluntary external anal sphincter relaxed, defecation can occur. Additional coordinated muscle activity also occurs and includes contraction of the diaphragm against a closed glottis, tensing of the abdominal wall, and relaxation of the pelvic floor.

The enteric nervous system plays an important role in the movement of bowel contents through the gastrointestinal (GI) tract as well. Smooth muscles in the GI tract have spontaneous electrical, rhythmic activity, resembling pacemakers in the stomach and small intestine, that communicate with the remainder of the bowel. There are both submucosal and myenteric plexuses of nerves. These nerves are connected to the central nervous system through sympathetic ganglia, splanchnic nerves, and parasympathetic fibers in the vagus nerve and the presacral plexus. Opioid medications affect the myenteric plexus, which coordinates peristalsis. Therefore, peristalsis is decreased and stool transit time is decreased, leading to harder, dryer, and less frequent stools, or constipation.1-3,9

Important factors that promote normal functioning of the bowel include the following:

1. Fluid intake. Nine liters of fluid (which includes 7 liters secreted from the salivary glands, stomach, pancreas, small bowel, and biliary system, and the average oral intake of 2 liters) are reduced to 1.5 liters by the time they reach the colon. At this point, water and electrolytes continue to be absorbed, and the end volume for waste is 150 mL. Therefore, decreased fluid intake can make a significant difference in the development of constipation.

2. Adequate dietary fiber. The presence of food in the stomach initiates the muscle contractions and secretions from the biliary, gastric, and pancreatic systems that lead to movement of the bowels. The amount of dietary fiber consumed is related to stool size and consistency.10

3. Physical activity. Colonic propulsion is related to intraluminal pressures in the colon. Lack of physical activity and reduced intraluminal pressures can significantly reduce propulsive activity.11

4. Adequate time or privacy to defecate. Changes in normal bowel routines, such as morning coffee or reading the paper, can decrease peristalsis and lead to constipation. Emotional disturbances are also known to affect gut motility.10

Primary, Secondary, and Iatrogenic Constipation

Cimprich10 offered three classifications of constipation:

1. Primary constipation is caused by reduced fluid and fiber intake, decreased activity, and lack of privacy.

2. Secondary constipation is related to pathological changes. These changes may include tumor, partial intestinal obstruction, metabolic effects of hypercalcemia, hypothyroidism, hypokalemia, as well as spinal cord compression at the level of the cauda equina or sacral plexus.

3. Iatrogenically induced constipation is related to pharmacological interventions. Opioids are the primary medications associated with constipation. In addition, Vinca rosea alkaloid chemotherapies (vin-cristine), anticholinergic medications (belladonna, antihistamines), tricyclic antidepressants (nortriptyline, amitriptyline), neuroleptics (haloperidol and chlorpromazine), antispasmodics, anticonvulsants (phenytoin and gabapentin), muscle relaxants, aluminum antacids, iron, diuretics (furosemide), and antiparkinsonian agents cause constipation.1,3,9

Constipation Related to Cancer and Its Treatment

Multiple factors associated with cancer and its treatment cause constipation. When it primarily involves the GI system or is anatomically associated with the bowel, cancer itself causes constipation. Pelvic cancers, including, ovarian, cervical, and uterine cancers, are highly associated with constipation and mechanical obstruction.10 Malignant ascites, spinal cord compression, and paraneoplastic autonomic neuropathy also cause constipation. Cancer-related causes include surgical interruption of the GI tract, decreased activity, reduced intake of both fluids and food, changes in personal routines associated with bowel movements, bed rest, confusion, and depression.1,3,8,10,14
Opioid-Related Constipation

Opioids affect bowel function primarily by inhibiting propulsive peristalsis through the small bowel and colon. McMillan and Williams found that 100% of the patients in their study who had received at least 30 mg of morphine in the previous 24 hours developed constipation. Opioids bind with the receptors on the smooth muscles of the bowel, affecting the contraction of the circular and longitudinal muscle fibers that cause peristalsis or the movement of contents through the bowel. Colonic transit time is lengthened, contributing to increased fluid and electrolyte absorption and dryer, harder stools. Peristaltic changes occur 5 to 25 minutes after administration of the opioid and are dose related. Patients do not develop tolerance to the constipation side effects even with long-term use of opioids. There is new evidence, particularly associated with transdermal fentanyl use, that constipation severity may differ among opioids. The use of laxatives and stool softeners with opioids represents a rational, proactive approach to opioid-induced constipation.

Assessment of Constipation

History

The measurement of constipation requires more than assessing the frequency of stools alone. Managing constipation requires a thorough history and physical examination. The use of a quantifying tool can be helpful in understanding what the patient is experiencing and how different that may be from the usual or baseline bowel habit. A tool developed in 1989, the Constipation Assessment Scale (CAS), has been tested for validity and reliability and found to have a significant ability to measure constipation as well as its severity between moderate and severe constipation. It is a simple questionnaire that requires 2 minutes to complete (Figure 11–1). The CAS includes eight symptoms associated with constipation: (1) abdominal distention or bloating, (2) change in amount of gas passed rectally, (3) less frequent bowel movements, (4) oozing liquid stool, (5) rectal fullness or pressure, (6) rectal pain with bowel movement, (7) small volume of stool, and (8) inability to pass stool. These symptoms are rated as 0, not experienced; 1, some problem; or 2, severe problem. A score between 0 and 16 is calculated and can be used as an objective measurement of subjective symptoms for ongoing management.

The CAS gives a good sense of bowel function. Sykes also outlines similar questions to use in taking a constipation history. It is important to start by asking patients when they moved their bowels last and to follow up by asking what their normal movement pattern is. Remember, what is considered constipated for one person is not for someone else. What are the characteristics of their stools and did they note any blood or mucus? Were their bowels physically difficult to move? This is especially important if they have cancer in or near the intestines or rectal area that may contribute to physical obstruction. Ovarian cancer patients usually complain of feeling severely bloated. They may say things like “If you stick a pin in me, I know I will pop!” Evaluating the abdomen or asking patients if they feel bloated or pressure in the abdomen is important. Does the patient feel pain when moving the bowels?

Medication- or Disease-Related History

The patient’s medical status and anticipated disease process are important in providing insight into areas where early intervention could prevent severe constipation or even obstruction. Constipation may be anticipated with primary and secondary bowel cancer, as well as with pelvic tumors, peritoneal mesothelioma or spinal cord compression, previous bowel surgery, or a history of Vinca alkaloid chemotherapy. Changes in dietary habits related to the above medications or the addition of new medications may contribute to constipation. Anticholinergic medications, antihistamines, tricyclic antidepressants, aluminum antacids, and diuretics can cause constipation. Hypercalcemia and hypokalemia contribute to constipation by slowing down motility. Ask patients if there are things they do to aid in defecation. Sometimes physical actions the patient may use can help causes related to rectocele, or rectal ulcer.

Physical Examination

Begin the physical examination in the mouth, to ensure that the patient is able to chew foods and that there are no lesions or tumors in the mouth that could interfere with eating. Does the patient wear dentures? Patients who wear dentures and have lost a great deal of weight may have dentures that do not fit properly, which would make eating and drinking difficult. Patients may choose to eat only what they are able to chew as a result of their dentures or other dental problems. Therefore, they may not be eating enough fiber and, thus, contributing to primary constipation.

Abdominal Examination. Inspect the abdomen initially for bloating, distention, or bulges. Distention may be associated with obesity, fluid, tumor, or gas. Remember, the patient should have emptied the bladder. Auscultation is important to evaluate the presence or absence of bowel sounds. If no bowel sounds are heard initially, listen continuously for a minimum of 5 minutes. The absence of bowel sounds may indicate a paralytic ileus. If the bowel sounds are hyperactive, it could indicate diarrhea. Percussion of the bowel may result in tympany, which is related to gas in the bowel. A dull sound is heard over intestinal fluid and feces. Palpation of the abdomen should
start lightly; look for muscular resistance and abdominal tenderness. This is usually associated with chronic constipation. If rebound tenderness is detected with coughing or light palpation, peritoneal inflammation should be considered. Deep palpation may reveal a “sausage-like” mass of stool in the left colon. Feeling stool in the colon indicates constipation. Although Sykes\(^\text{15}\) points out that the distinction between tumor and stool is hard to make, recognizing the underlying anatomy is helpful in distinguishing the stool along the line of the descending colon or more proximal colon, including the cecum. A digital examination of the rectum may reveal stool or possible tumor or rectocele. If the patient is experiencing incontinence of liquid stool, obstruction must be considered. Examining for hemorrhoids, ulcerations, or rectal fissures is important, especially in the neutropenic patient. Patients with a neutropenia can complain of rectal pain well before a rectal infection is obvious. Evaluating the patient for infection, ulceration, or rectal fissures is very important. Additionally, determine whether the patient has had previous intestinal surgery, alternating diarrhea and constipation, complaints of abdominal colic pain or nausea, and vomiting. Examining the stool for shape and consistency can also be useful. Stools that are hard and pellet-like suggest slow transit time, whereas stools that are ribbon-like suggest hemorrhoids. Blood or mucus in the stool suggests tumor, hemorrhoids, or possibly a preexisting colitis.\(^\text{15}\) Elderly patients may experience urinary incontinence related to fecal impaction.\(^\text{1,2,14}\) Abdominal pain may also be related to constipation. Patients will complain of colic pain related to the effort of colonic muscle to move hard stool. The history may be complicated by known abdominal tumors. Patients in pain should still be treated with opioids as needed.

---

<tbody>
<tr>
<td>Decreased appetite, decreased fluid intake, low-fiber diet, weakness, inactivity, confusion, depression, change in normal toileting habits</td>
</tr>
</tbody>
</table>

**Etiology**

| Decreased fluid and food intake leading to dehydration and weakness. Decreased intake, ineffective voluntary elimination actions, as well as decreased normal defecation reflexes. Decreased peristalsis; increased colonic transit time leads to increased absorption of fluid and electrolytes and small, hard, dry stools. Inactivity, weakness, changes in normal toileting habits, daily bowel function reflexes, and positioning affect ability to use abdominal wall musculature and relax pelvic floor for proper elimination. Psychological depression can increase constipation by slowing down motility. |

Management of Constipation

Preventing constipation whenever possible is the most important management strategy. Constipation can be extremely distressing to many patients and severely affects quality of life. The complicating factor remains the individuality of a patient’s response to constipation therapy. Therefore, there is no set rule for the most effective way to manage constipation. Patients with primary bowel cancers, pelvic tumors such as ovarian or uterine cancers, or metastatic tumors that press on colon structures will experience a difficult-to-manage constipation. It is not unusual for those patients to be admitted to the hospital to manage constipation and to rule out obstruction. To minimize those admissions whenever possible, as Dame Cicely Saunders, the founder of hospice recommends, “Do not forget the bowels.” Nurses are at the bedside most often and are the ones who see the cumulated number and types of medication a patient may be taking. Understanding which medications and disease processes put a patient at high risk for constipation is essential for good bowel management.

Assessing the patient’s constipation as discussed earlier is the best place to start. The patient’s problem list should reflect the risk for constipation and the need for aggressive constipation management. For example, diabetic patients who are taking opioids for pain are at extremely high risk for constipation. Diabetes damages the sensory fibers that are most important for temperature and pain sensation. The neuronal influence on intestinal motility is also affected through diabetes.\(^2,6,10\)

In addition to assessing the extent of the patient’s constipation, determining the methods the patient has used to manage the constipation in the past is essential. This can usually provide information regarding what medications the patient tolerates best and where to start with recommendations for management. According to Sykes,\(^8\) using radiography to evaluate whether constipation has advanced to obstruction may be useful if there is indecision, but in palliative medicine the use of x-ray procedures should be limited. He also suggests that blood work be limited to corrective studies; for example, if hypercalcemia or hyperkalemia can be reversed to improve constipation, such blood work may be useful.

Improving three important primary causes of constipation is essential. Encouraging fluid intake is a priority. Increasing or decreasing fluid intake by as little as 100 mL can contribute to constipation.\(^1,15\) Increase dietary intake as much as possible. This is a difficult intervention for many patients. Focusing on food intake for some patients can increase their anxiety and discomfort. If a patient feels that bowel movements are less frequent, think about dietary intake. The Western diet is fiber-deficient.\(^1,5,11,15\) Caution is needed for patients who use bulk laxatives such as psyllium, especially if they also are taking other bowel medications. Increasing the fiber intake for patients in general may be helpful, but in palliative care, high fiber in the diet can cause more discomfort and constipation. Fiber without fluid absorbs what little liquid the patient may have available in the bowel and makes the bowels more difficult to move.\(^1,2,8\) For example, an elderly patient who experiences reduced appetite and decreased fluid intake related to chemotherapy or disease, and whose symptoms are nausea or vomiting with reduced activity, is at extreme risk for constipation. Encouraging activity whenever possible, even in end-of-life care, can be very helpful. Increased activity helps to stimulate peristalsis and to improve mood.\(^1,7\) Physical therapy should be used as part of a multidisciplinary bowel-management approach. Providing basic range of motion, either active or passive, can improve bowel management and patient satisfaction.\(^2,11\)

Pharmacological Management

Types of Laxatives

**Bulk Laxatives.** Laxatives can be classified by their actions. Bulk laxatives do just that—they provide bulk to the intestines to increase mass, stimulating the bowel to move. Increasing dietary fiber is considered a bulk laxative. The recommended dose of bran is 8 g daily. Other bulk laxatives include psyllium, carboxymethylcellulose, and methylcellulose.\(^13\) Bulk laxatives are more helpful for mild constipation. Because bulk laxatives work best when patients are able to increase their fluid intake, they may be inappropriate for end-stage patients. In palliative care, patients may not ingest enough fluid. It is recommended that the patient increase fluids by 200 to 300 mL when using bulk laxatives. Patients may have difficulty with the consistency of bulk laxatives and find this approach unacceptable. Patients using bulk laxatives without the additional fluid intake are at risk of developing a partial bowel obstruction or, if an impending one exists, may risk complete bowel obstruction. The benefits of bulk laxatives in severe constipation are questionable.

Additional complications include allergic reactions, fluid retention, and hyperglycemia.\(^1\) Bulk laxatives produce gas as the indigestible or nonsoluble fiber breaks down or ferments. The result can be uncomfortable bloating and gas.

The recommended dosage of bulk laxatives is to start with 8 g daily, then stabilize at 3 to 4 g for maintenance.

Psyllium is recommended at 2 to 4 teaspoons daily as a bulk laxative. Action may take 2 to 3 days.

**Lubricant Laxatives.** Mineral oil is probably the most common lubricant laxative used. It can help by both lubricating the stool surface and softening the stool by penetration, leading to an easier bowel movement. Overuse of mineral oil can cause seepage from the rectum and perineal irritation. With chronic use it can lead to malabsorption of fat-soluble vitamins (vitamins A, D, E, and K). Levy\(^4\) recommends caution when giving mineral oil at bedtime or giving it to patients at risk for aspiration. Aspiration pneumonitis or lipid pneumonia is common in the frail and elderly patient. A complication should be noted when mineral oil is given with docusate. If patients are on daily docusate (Colace) and are given mineral oil in addition to assist with constipation, the absorption of...
mineral oil increases, leading to a risk of lipoid granuloma in the intestinal wall.  

The recommended dosage of mineral oil is 10 to 30 mL/day, and action may occur in 1 to 3 days.

**Surfactant/Detergent Laxatives.** Surfactant/detergent laxatives reduce surface tension, which increases absorption of water and fats into dry stools, leading to a softening effect. According to Levy and others,\(^5\) medications such as docusate exert a mucosal contact effect, which encourages secretion of water, sodium, and chloride in the jejunum and colon and decreases electrolyte and water reabsorption in the small and large intestine.\(^4\) At higher doses, these laxatives may stimulate peristalsis. Docusate is used in a compounded or fixed combination with bowel stimulants like casanthranol (Peri-Colace) or senna (Senokot S). Castor oil also works like a detergent laxative by exerting a surface-wetting action on the stool and directly stimulates the colon, but Levy discourages its use in cancer-related constipation because results are difficult to control.

The recommended dosage of surfactant/detergent laxatives includes docusate (Colace) starting at 300 mg daily and calcium salt (Survak) at 240 mg daily to twice a day. (This may take 1 to 3 days to be effective.)

**Combination Medications.** Peri-Colace is a combination of a mild stimulant laxative, casanthranol, and the stool softener docusate (Colace). Combination softener/laxative medications have been shown to be more effective than softeners alone at a lower total dose.\(^9\)

The recommended dosage of Senokot S is two tablets daily to twice a day (see Senokot S flow chart in Table 11–2). Senokot S is a combination of senna as a laxative and a stool softener for smoother and easier evacuation. Results occur in 6 to 12 hours. Flexibility of dosing allows individual needs to be met.

**Osmotic Laxatives.** Osmotic laxatives are nonabsorbable sugars that exert an osmotic effect in both the small and, to a lesser extent, the large intestines. They have the additional effect of lowering ammonia levels. This is helpful in improving confusion, especially in hepatic failure patients. According to Levy,\(^1\) 30 mL of lactulose can increase the colon volume by 400 to 600 mL within 1 to 3 hours. These laxatives can be effective for chronic constipation, especially when related to opioid use. Drawbacks of these agents are that effectiveness is completely dose-related and, for some patients, the sweet taste is intolerable. The bloating and gas associated with higher doses may be too uncomfortable or distressing to tolerate. Lactulose or sorbitol can be put into juice or other liquid to lessen the taste. Patients may prefer hot tea or hot water to help reduce the sweet taste. Lactulose is more costly than sorbitol liquid. A study that compared the two medications found that there was no significant difference, except with regard to nausea, which increased with lactulose (\(P = 0.05\)).\(^17\)

The recommended dosage of lactulose/sorbitol is 30 to 60 mL initially for severe constipation every 4 hours until a bowel movement occurs. Once that happens, calculate the amount of lactulose used to achieve that movement, and then divide in half for recommended daily maintenance dose.\(^1\) An example would be: it took 60 mL to have a bowel movement, therefore 30 mL daily should keep the bowels moving regularly. Action can occur within 4 hours, depending on the dose. Polyethylene glycol (MiraLax) is used frequently and can be sprinkled over food. Recommended dose is 240 mL daily should keep the bowels moving regularly. Action can occur within 4 hours, depending on the dose. Polyethylene glycol (MiraLax) is used frequently and can be sprinkled over food. Recommended dose is 240 mL

Source: Adapted from Levy (1991), reference 1.
Suppositories should never be used in patients with severely reduced white cell or platelet counts due to the risk of bleeding or infection.

**Saline Laxatives.** Magnesium hydroxide (milk of magnesia) and magnesium citrate are the most commonly used saline laxatives. They increase gastric, pancreatic, and small intestinal secretion, as well as motor activity throughout the intestine. Aluminum salts in many of the antacid medications counteract the laxative effect of magnesium. This laxative can also cause severe cramping and discomfort. This medication is recommended for use only as a last resort in chronically ill patients. Opioid-related constipation requires the use of aggressive laxatives earlier rather than later to prevent severe constipation, referred to as obstipation, which leads to obstruction.

The recommended dosage of milk of magnesia is 30 mL to initiate a bowel movement. For opioid-related constipation, 15 mL of milk of magnesia may be added to the baseline bowel medications either daily or every other day. Magnesium citrate comes in a 10-ounce bottle. For severe constipation, it is used as a one-time initial therapy. It can be titrated up or down, depending on patient response. For patients with abdominal discomfort or pain, it is recommended that obstruction be ruled out before using this medication. If the patient were obstructed, even only partially, this would only increase the discomfort or lead to perforation.

**Bowel Stimulants.** Bowel stimulants work directly on the colon to increase motility. These medications stimulate the myenteric plexus to induce peristalsis. They also reduce the amount of water and electrolytes in the colon. They are divided into two groups: the diphenylmethanes and the anthraquinones. The diphenylmethanes are commonly known as phenolphthalein (Ex-Lax, Fen-a-Mint, Correctol, and Doxidan) and bisacodyl (Dulcolax). Phenolphthalein must be metabolized in the liver (lactulose, Cephylac) is helpful when a large amount of stool is present. This may help to push the stool through the GI tract.

**Suppository Medications.** As discussed above, bisacodyl (Dulcolax) comes in a suppository. Although the thought of rectal medications is unpleasant for many patients, suppositories’ quick onset of action makes them more acceptable. Bisacodyl comes in 10 mg for adults and 5 mg as a pediatric dose.

Liquid rectal laxatives or lubricants should be used infrequently. In severely constipated patients, they may be necessary. Most commonly, saline enemas are used to loosen the stool and to stimulate rectal or distal colon peristalsis. Repeated use can cause hypocalcemia and hyperphosphatemia, so it is important to use enemas cautiously. Enemas should never be considered part of a standing bowel regimen.

Oil retention enemas, however, are particularly helpful for severely constipated patients, for whom disimpaction may be necessary. They work best when used overnight, to allow softening. Overnight retention is effective only if the patient is able to retain it that long. The general rule is that the longer the enema is retained, the better the results. Bisanz10 recommends a milk-and-molasses enema (Figure 11–2) for patients with low impaction to ease stool evacuation in a nonirritating way. It is a low-volume enema of 300 mL and therefore thought to cause less cramping.

Combining an enema with an oral saline-type cathartic (lactulose, Cephylac) is helpful when a large amount of stool is present. This may help to push the stool through the GI tract.

If disimpaction is necessary, remember that it can be extremely painful; therefore, premedicate the patient with either opioid and/or benzodiazepine anxiolytics to reduce physical and emotional pain.

There are few studies outlining the efficacy of one enema over another. The reported success rates for rectal enemas

---

**Figure 11–2.** Milk and molasses enema recipe. **Sources:** Bisanz (1997), reference 10; Lowell (2003), reference 23; Walsh (1989), reference 50.

**MILK and MOLASSES ENEMA RECIPE**

8 oz. warm water
3 oz. powdered milk
4.5 oz. molasses

- Put water and powdered milk in a plastic jar. Close the jar and shake until the water and milk appear to be fully mixed.
- Add molasses, and shake the jar again until the mixture appears to have an even color throughout.
- Pour mixture into enema bag. Administer enema high by gently introducing tube about 12 inches. Do not push beyond resistance. Repeat every 6 hours until good results are achieved.
within 1 hour includes phosphate enemas (100%), mini-enemas
(Micralax) (95%), bisacodyl suppositories (66%), and glycerine
suppositories (38%).16 If none of the above enemas is effective,
Sykes9 recommends rectal lavage with approximately 8
liters of warmed normal saline. It is important to remember
that if a patient’s constipation requires this invasive interven-
tion, you must change the usual bowel regimen once this bowel
crisis is resolved. For severe constipation associated with opio-
oids, Levy4 suggests four Senokot S and three Dulcolax tablets
times three a day and 60 mL of lactulose every other night for a
goal of a bowel movement every other day (see Table 11–2).

New Approaches to Constipation Management

Oral naloxone has been studied for the treatment of opioid-
related constipation resistant to other treatments. Culpepper-
Morgan and colleagues19 found that the majority of opioid
effect on the human intestine is mediated peripherally rather
than centrally. Naloxone, which is an opioid antagonist, has
less than 1% availability systemically when given orally, due to
the first-pass effect in the liver. Therefore, the risk of causing a
withdrawal response when using naloxone orally is small.
Although the risk is small, patients who are opioid-dependent
must be monitored closely for signs of withdrawal.2 It has been
recommended that the dose start with 1 mg twice per day
and be titrated as a percentage of the current morphine dose.
Titration of dose to a maximum of 12 mg at least 6 hr apart
may be needed to avoid adverse reactions.19 The cost of oral
naloxone also prohibits its use beyond rare circumstances.
Using naloxone in the outpatient setting is not recommended
because of the increased risk of withdrawal or dose-benefit
behavior.19 Future studies will look at alternative drugs from
the same class that do not cross the blood–brain barrier and
that may offer more effective results.15

Oral erythromycin has been shown to cause diarrhea in 50% of
patients who use it as an antibiotic.15 Currently, researchers
are investigating its use to promote diarrhea. There is also inter-
est in identifying a medication that would increase colon transit
time without being antibacterial.

Many herbal medicines have laxative properties, such as
mulberry and constituents of rhubarb, which are similar to
senna. These herbs are being evaluated for use as laxatives.
Patients have been known to develop rashes; in one patient,
changes were found in warfarin (Coumadin) levels that were
related to natural warfarin found in a laxative tea. Many patients
prefer these options instead of pharmaceutical laxatives, but
they should be cautious about where they purchase any herbal
product and be alert to any unexplained side effects, as their
content is unregulated.

Nursing Interventions for Constipation

Nurses should always be proactive in initiating laxative ther-
apy. Bowel function requires continued evaluation to follow
the trajectory of the disease and the changes that occur in nor-
mal activities that affect bowel function. Nurses should also be
alert to medications that can increase the risk of constipation
(see Table 11–1). Some patients, especially those on long-term
opioid therapy, sometimes need at least two different regimens
that can be interchanged when one or the other loses its effec-
tiveness for a time. Like opioids, over time, a standing laxative
regimen may be less effective if tolerance develops.1,15 It is also
important to be aware of medication dosing changes, as it is
common to forget to increase anticonstipation therapy when
there is an increase in opioid therapy. Patients generally have
increased risk of constipation when opioids are increased. Position-
ing patients to allow gravity to assist with bowel movements
is helpful. Assisting with oral fluid intake as well as dietary inter-
ventions are both helpful. Discuss patients’ management needs
as well as personal cultural perspectives and factors that may
contribute to good bowel hygiene. Exercise within each patient’s
tolerance is recommended to aid in elimination. Fatigue,
advanced disease, and decreased endurance all play a role in
obstructing good bowel maintenance. The importance of effec-
tive bowel management cannot be stressed enough. It remains
the most distressing symptom in end-stage cancer patients.

DIARRHEA

Diarrhea has been a major symptom and significant problem
associated with newer chemotherapeutic and biological and
radiation treatment regimens.20,24 It is a main symptom of 7%
to 10% of hospice admissions.15 Overgrowth of GI infections
such as Candida can cause diarrhea as well.15 Treating diarrhea
requires a thorough assessment and therapy directed at the
specific cause. Diarrhea is usually acute and short-lived, last-
ing only a few days, as opposed to chronic diarrhea, which lasts
3 weeks or more.24 Diarrhea can be especially severe in human
immunodeficiency virus (HIV)–infected patients. Forty-three
percent of bone marrow transplant patients develop diarrhea
related to radiation or graft versus host disease (GVHD).25
Similar to constipation, this symptom can be debilitating and
can severely affect quality of life.18,20 Diarrhea can prevent
patients from leaving their homes, increase weakness and
dehydration, and contribute to feelings of lack of control and
depression. Nurses play a significant role in recognizing, edu-
cating, and managing diarrhea and its manifestations.

Definitions

Diarrhea is described as an increase in stool volume and liq-
uidity resulting in three or more bowel movements per day.1,24
Secondary effects related to diarrhea include abdominal
cramps, anxiety, lethargy, weakness, dehydration, dizziness,
loss of electrolytes, skin breakdown and associated pain, dry
mouth, and weight loss. Diarrhea varies among patients depend-
ing on their bowel history. Acute diarrhea occurs within 24 to
48 hours of exposure to the cause and resolves in 7 to 14 days.
Chronic diarrhea usually has a late onset and lasts 2 to 3 weeks, with an unidentified cause.

Prevalence and Impact

Cancer patients may have multiple causes of diarrhea. It may be due to infections or related to tumor type or its treatment. A common cause of diarrhea is overuse of laxative therapy or dietary fiber. Additional causes include malabsorption disorders, motility disturbances, stress, partial bowel obstruction, enterocolic fistula, villous adenoma, endocrine-induced hypersecretion of serotonin, gastrin calcitonin, and vasoactive intestinal protein prostaglandins. Treatment-related causes include radiation and chemotherapy, which cause overgrowth of bacteria, with endotoxin production that has a direct effect on the intestinal mucosa. Local inflammation and increased fluid and electrolyte secretion occur, resulting in interference on the intestinal mucosa. Secretory diarrhea is most associated with chemotherapy and radiation therapy. The cause is related to mechanical damage to the epithelial crypt cells in the GI tract, The necrosis that results, along with the inflammation and ulceration of the intestinal mucosa, leads to further damage related to exposure to bile and susceptibility to opportunistic infections, atrophy of the mucosal lining, and fibrosis. This all contributes to loss of absorption due to damaged villi, causing an increase in water, electrolytes, mucus, blood, and serum to be pulled into the intestine from immature crypt cells, and increased fluid secretion, resulting in diarrhea.

Diarrhea associated with radiation can occur by the 2nd or 3rd week of treatment and can continue after radiation has been discontinued. Radiation-induced diarrhea is related to focus of radiation and total of radiation dose. Pelvic radiation alone has been shown to cause diarrhea of any grade in up to 70% of the patients receiving it. A grade 3 or 4 diarrhea is associated with approximately 20% of those patients. The risk is increased in acquired immunodeficiency syndrome (AIDS), GVHD, or HIV patients. The end result could be a change in the intestinal mucosa that results in a limited ability to regenerate epithelium, which can lead to bleeding and ileus. The damaged mucosa leads to increased release of prostaglandins and malabsorption of bile salts, increasing peristaltic activity.

Surgical patients who have had bowel-shortening procedures or gastrectomy related to cancer experience a “dumping syndrome,” which causes severe diarrhea. This type of diarrhea is related to both osmotic and hypermotile mechanisms. Patients may experience weakness, epigastric distention, and diarrhea shortly after eating. The shortened bowel can result in a decreased absorption capacity and an imbalance in absorptive and secretory function of the intestine.

Pathophysiology

Diarrhea can be grouped into four types, each with a different mechanism: osmotic diarrhea, secretory diarrhea, hypermotile diarrhea, and exudative diarrhea. Cancer patients rarely exhibit only one type. Understanding the mechanism of diarrhea permits more rational treatment strategies.

Osmotic Diarrhea. Osmotic diarrhea is produced by intake of hyperosmolar preparations or nonabsorbable solutions such as enteral feeding solutions. Enterocolic fistula can lead to both osmotic diarrhea from undigested food entering the colon and hypermotile diarrhea. Hemorrhage into the intestine can cause an osmotic-type diarrhea because intraluminal blood acts as an osmotic laxative. Osmotic diarrhea may result from insufficient lactase when dairy products are consumed.

Secretory Diarrhea. Secretory diarrhea is most associated with chemotherapy and radiation therapy. The cause is related to mechanical damage to the epithelial crypt cells in the GI tract. The necrosis that results, along with the inflammation and ulceration of the intestinal mucosa, leads to further damage related to exposure to bile and susceptibility to opportunistic infections, atrophy of the mucosal lining, and fibrosis. This all contributes to loss of absorption due to damaged villi, causing an increase in water, electrolytes, mucus, blood, and serum to be pulled into the intestine from immature crypt cells, and increased fluid secretion, resulting in diarrhea.

Secretory diarrhea is the most difficult to control. Malignant epithelial tumors producing hormones that can cause diarrhea include metastatic carcinoid tumors, gastrinoma, and medullary thyroid cancer. The primary effect of secretory diarrhea is related to the hypersecretion stimulated by endogenous mediators that affect the intestinal transport of water and electrolytes. This results in accumulation of intestinal fluids.

Partial bowel obstruction from abdominal malignancies can cause a reflex hypermotility that may require bowel-quieting medications such as loperamide. Enterocele fistula can lead to diarrhea from irritative hypermotility and osmotic influence of undigested food entering the colon.
Biliary or pancreatic obstruction can cause incomplete digestion of fat in the small intestine, resulting in interference with fat and bile salt malabsorption, leading to hypermotile diarrhea, also called steatorrhea. Malabsorption is related to pancreatic cancer, gastrectomy, ileal resection or colectomy, rectal cancer, pancreatic islet cell tumors, or carcinoid tumors. Chemotherapy-induced diarrhea is frequently seen with 5-fluorouracil or N-phosphonoacetyl-l-aspartate. High-dose cisplatin and irinotecan (Camptosar<sup>TM</sup>) cause severe hypermotility. Other chemotherapy drugs that cause diarrhea include cytosine arabinoside, nitrosourea, methotrexate, cyclophosphamide, doxorubicin, daunorubicin, hydroxyurea and biotransport-2, interferon and topoisomerase inhibitors (capecitabine [5-FU prodrug]), oxaliplatin.<sup>20,22</sup>

**Exudative Diarrhea.** Radiation therapy of the abdomen, pelvis, or lower thoracic or lumbar spine can cause acute exudative diarrhea.<sup>24</sup> The inflammation caused by radiation leads to the release of prostaglandins. Treatment using aspirin or ibuprofen was shown to reduce prostaglandin release and decrease diarrhea associated with radiation therapy.<sup>24</sup> Bismuth subsalicylate (Pepto-Bismol) is also helpful for diarrhea caused by radiotherapy.<sup>10</sup>

According to Sykes,<sup>15</sup> there are multiple causes of diarrhea in palliative medicine. Concurrent diseases such as diabetes mellitus, hyperthyroidism, inflammatory bowel disease, irritable bowel syndrome, and GI infection (C. difficile) can contribute to the development of diarrhea. Finally, the dietary influences of fruit, bran, hot spices, and alcohol, as well as over-the-counter medications, laxatives, and herbal supplements, need to be considered as sources of diarrhea.<sup>15,24</sup>

**Assessment of Diarrhea**

Diarrhea assessment requires a careful history to detail the frequency and nature of the stools. The National Cancer Institute Scale of Severity of Diarrhea uses a grading system from 0 to 4. Stools are rated by (1) number of loose stools per day and (2) symptoms (Table 11–3). This scale permits an objective score to define the severity of diarrhea.

The initial goal of assessment is to identify and treat any reversible causes of diarrhea. If diarrhea occurs once or twice a day, it is probably related to anal incontinence. Large amounts of watery stools are characteristic of colonic diarrhea. Pale, fatty, malodorous stools, called steatorrhea, are indicative of malabsorption secondary to pancreatic or small-intestinal causes. If a patient who has been constipated complains of sudden diarrhea with little warning, fecal impaction with overflow is the probable cause.<sup>15,24</sup>

Evaluate medications that the patient may be taking now or in the recent past. Is the patient on laxatives? If the stools are associated with cramping and urgency, it may be the result of peristalsis-stimulating laxatives. If stools are associated with fecal leakage, it may be the result of overuse of stool-softening agents such as Colace.<sup>15,24</sup>

Depending on the aggressiveness of the treatment plan, additional assessment could include stool smears for pus, blood, fat, ova, or parasites. Stool samples for culture and sensitivity testing may be necessary to rule out additional sources of diarrhea through C. difficile toxin, Giardia lamblia, or other types of GI infection.<sup>1</sup> If patients have diarrhea after 2 to 3 days of fasting, secretory diarrhea should be evaluated. Osmotic and secretory causes are considered first; if ruled out, then hypermotility is the suspected mechanism.

**Management of Diarrhea**

A combination of supportive care and medication may be appropriate for palliative management of diarrhea. The goal of diarrhea management should focus on minimizing or eliminating the factors causing the diarrhea, providing dietary interventions, and maintaining fluid and electrolyte balance as appropriate. Quality-of-life issues include minimizing skin breakdown or infections, relieving pain associated with frequent diarrhea, and maintaining the patient’s dignity.<sup>24</sup>

If the patient is dehydrated, oral fluids are recommended over the IV route.<sup>15</sup> Oral fluids should contain electrolytes and a source of glucose to facilitate active electrolyte transport (Figure 11–3).

Following diarrhea, the diet should start with clear liquids, flat lemonade, ginger ale, and toast or simple carbohydrates. It is recommended that the patient avoid milk if diarrhea is related to infection due to acute lactase deficiency. Protein and fats can be added to the diet slowly as diarrhea resolves. Dietary management may help minimize amount of diarrhea.

Medication Recommendations

There are many nonspecific diarrhea medications that should be used unless infections are suspected as the cause. If Shigella or C. difficile are responsible, nonspecific antidiarrheal medications can make the diarrhea worse. Loperamide (Imodium) has become the drug of choice for the treatment of nonspecific diarrhea. It is a long-acting opioid agonist. The 2-mg dose has the same antidiarrheal action as 5 mg, two tablets of diphenoxylate, or 45 mg of codeine. The usual management of diarrhea begins with 4 mg of loperamide, with one capsule following each loose bowel movement. Most diarrhea is managed by loperamide 2 to 4 mg once to twice a day.

Diphenoxylate (Lomotil 2.5 mg with atropine 0.025 mg) is given as one or two tablets orally as needed for loose stools, maximum of eight/day. Diphenoxylate is derived from meperidine and binds to opioid receptors to reduce diarrhea. Atropine was added to this antidiarrheal to prevent abuse. Diphenoxylate is not recommended for patients with advanced liver disease because it may precipitate hepatic coma in patients with cirrhosis. Neither diphenoxylate nor loperamide is recommended for use in children under 12 years old. Codeine as an opioid for the reduction of diarrhea can be helpful. It is also less expensive than some opioid medications. Most cancer-related diarrheas respond well to this drug. For specific mechanisms, other medications might be more beneficial. Tincture of opium works to decrease peristalsis, given at .6 mL every 4 to 6 hours. This is a controlled substance but may also provide some pain relief. Absorbent agents such as pectin and methylcellulose may help provide bulk to increase consistency of the stools.

Anticholinergic drugs such as atropine and scopolamine are useful to reduce gastric secretions and decrease peristalsis. Somatostatin analogues such as octreotide (Sandostatin) are also effective for secretory diarrhea that may result from endocrine tumors, AIDS, GVHD, or post-GI resection. They may be helpful for patients who experience painful cramping. Side effects of that class of drug can complicate their use: dry mouth, blurred vision, and urinary hesitancy.

Mucosal antiprostaglandin agents such as aspirin, indomethacin, and bismuth subsalicylate (Pepto-Bismol) are useful for diarrhea related to enterotoxigenic bacteria, radiotherapy, and prostaglandin-secreting tumors. Octreotide (Sandostatin) is also effective for patients with AIDS, GVHD, diabetes, or GI resection. Octreotide is administered subcutaneously at a dose of 50 to 200 mg two or three times per day. Ranitidine is a useful adjuvant to octreotide for patients with Zollinger-Ellison syndrome with gastrin-induced gastric hypersecretion. Side effects include nausea and pain at injection site. Patients may also experience abdominal or headache pain. Clonidine is effective at controlling watery diarrhea in patients with bronchogenic cancer. Clonidine effects an α₂-adrenergic stimulation of electrolyte absorption in the small intestine. Streptozocin is used for watery diarrhea from pancreatic islet cell cancer because it decreases intestinal secretions. Hypermotile diarrhea involves problems with fat absorption. The recommended treatment is pancreatin before meals. Pancreatin is a combination of amylase, lipase, and protease that is available for pancreatic enzyme replacement. Lactaid may also be helpful for malabsorption-related diarrhea.

Nursing Interventions for Diarrhea

Nursing interventions should include nonpharmacological interventions focused on diet and psychosocial support (Tables 11–4 and 11–5).

| • \(\alpha_2\)-Adrenergic agonists—clonidine |

Report to nurse or physician if antidiarrheal medication seems ineffective

Psycosocial Interventions
Provide support to patient and family. Recognize negative effects of diarrhea on quality of life:

• Fatigue
• Malnutrition
• Alteration in skin integrity
• Pain and discomfort
• Sleep disturbances
• Limited ability to travel
• Compromised role within the family
• Decreased sexual activity
• Caregiver burden

• Evaluate medications currently being used to identify polypharmacy, where multiple medication side effects may be contributing to the problem.
• Minimize or prevent diarrhea accidents in an effort to reduce patient anxiety. Anticipate obstacles between the patient and the bathroom. Assist with access plans and timing needs. Recommend com-mode chair at bedside to allow easiest access and prevent falls or additional problems.
• Protecting the bed with Chux can be better accepted than diapers. It may also be better for skin integrity but requires multiple layers of Chux and drawsheets for best results.
• Applying skin ointment protection after cleaning and drying the area is also important. Thick protective creams that apply a barrier on the skin are most beneficial. Eucerin cream, zinc oxide, and bag balm are three that have been used anecdotally with success.
• The psychosocial impact of diapers can be devastating for some patients. Encourage a discussion with patient and family about patient needs, fears, and perceptions.
• Along with focus on diet/medications, skin integrity, and psychosocial needs, odor management must also be addressed. Perfumed air fresheners sometimes only make it worse. Concentrate on being sure the perineum or peristomy area is clean and the linens are not soiled. Also be sure that dirty linens or trash are removed from the room. Using aromatherapy such as lavender may be soothing.
• Remember that there may be times when adult diapers are essential and can help alleviate distress to the patient, for example, when traveling or on necessary outings. Remind families to check them frequently to prevent skin breakdown and, again, be sure there is skin barrier ointment applied before the diaper padding.

Conclusion
Managing diarrhea in the cancer patient is challenging at best. The nurse’s role in helping the patient and caregivers talk about this difficult symptom is essential. It is important to respect comfort levels about the topic among nurse, patient, and caregiver to allow information sharing. Goals of diarrhea therapy should be to restore an optimal pattern of elimination, maintain fluid and electrolyte balance as desired, preserve nutritional status, protect skin integrity, and ensure the patient’s comfort and dignity.\(10,30\)

MALIGNANT OBSTRUCTION
As primary tumors grow in the large intestine, they can lead to obstruction. Obstruction is related to the site and stage of...
disease. Tumors in the splenic flexure obstruct 49% of the time, but those in the rectum or rectosigmoid junction only 6% of the time. Obstruction can occur intraluminally related to primary tumors of the colon. Intramural obstruction is related to tumor in the muscular layers of the bowel wall. The bowel appears thickened, indurated, and contracted. Extramural obstruction is related to mesenteric and omental masses and malignant adhesions. The common metastatic pattern, in relation to primary disease in the pancreas or stomach, gener-
ally goes to the duodenum, from the colon to the jejunum and ileum, and from the prostate or bladder to the rectum.

**Definition**

Intestinal obstruction is occlusion of the lumen or absence of the normal propulsion that affects elimination from the GI tract. Motility disruption, either impaired or absent, leads to a mechanical obstruction but without occlusion of the intestinal lumen. Mechanical obstruction results in the accumulation of fluids and gas proximal to the obstruction. Distention occurs as a result of intestinal gas, ingested fluids, and digestive secretions. It becomes a self-perpetuating phenomenon as when distention increases, intestinal secretion of water and electrolytes increases. A small-bowel obstruction causes large amounts of diarrhea. The increased fluid in the bowel leads to increased peristalsis, with large quantities of bacteria growing in the intestinal fluid of the small bowel.

Obstruction is related to the surrounding mesentery or bowel muscle, such as in ovarian cancer. Additional factors include multiple sites of obstruction along the intestine to constipating medications (Table 11–6), fecal impaction, fibrosis, or change in normal flora of the bowel. The goal of treatment is to prevent obstruction from happening whenever possible.

**Prevalence and Impact**

The best treatment options for bowel obstruction in a patient with advanced cancer remain undetermined. As obstruction increases, bacteria levels increase and can lead to sepsis and associated multisystem failure and death. The difficulty is knowing which patients will truly benefit from surgical intervention. The impact of obstruction on the patient and family is overwhelming. The patient and caregivers have been aggressively trying to manage the patient’s constipation in an effort to prevent this very problem. Obstruction for patients means failure to manage constipation or a sign of growing disease. New interventions have been developed in an effort to provide additional noninvasive approaches for the management of bowel obstruction.

In a retrospective study, Jong and colleagues found that palliative surgery for bowel obstruction in advanced ovarian cancer achieved successful alleviation, defined as patient survival longer than 60 days after surgery, the ability to return home, and relief of bowel obstruction for longer than 60 days. Past studies associated with ovarian or abdominal cancers found survival rates in general to be less than 6 months. In patients for whom a definitive procedure could take place, such as a resection, bypass, colostomy, or ileostomy, the mean survival was 6 months. For these patients, who were not surgical candidates, the mean survival rate was 1.8 months. Progressive cancer was the cause of obstruction in 86% of patients. There was a postoperative complication rate of 49%, which included wound infection, enterocutaneous fistulae, and other septic sequelae. Median postoperative survival was 140 days. In general, the operative mortality rate for this group was 12% to 25%.

Further research needs to be done similar to that of Jong and colleagues, who evaluated the effects of surgical intervention on quality as well as quantity of life. The effect of unrelieved intestinal obstruction on quality of life for the patient and loved ones is devastating.

**Assessment and Management of Malignant Obstruction**

Patients may experience severe nausea, vomiting, and abdominal pain associated with a partial or complete bowel obstruction. In the elderly patient, fecal impaction may also cause urinary incontinence. General signs and symptoms associated with different sites of obstruction are listed in Table 11–6. Providing thoughtful and supportive interventions may be more appropriate than aggressive, invasive procedures. The signs and symptoms of obstruction may be acute, with nausea, vomiting, and abdominal pain. A majority of the time, however, obstruction is a slow and insidious phenomenon, which may progress from partial to complete obstruction. Palliative care should allow for a thoughtful and realistic approach to management of obstruction within the goals of care. Radiological examination should be limited unless...
surgery is being considered. The use of self-expanding metallic stents has been highly effective for malignant colorectal obstruction and, in some cases, has prevented the need for colostomy. It is done in interventional radiology and requires close clinical observation, since perforation is a potential complication. At the minimum, it has allowed emergent relief of obstruction for surgical intervention in the future. Putting a patient through an x-ray of the abdomen may be helpful to confirm the obstruction and identify where it is, but defining the goal of therapy is essential. When patients exhibit signs of obstruction, a physical exam may be helpful to assess the extent of the problem. Asking the patient for a bowel history, last bowel movement, and a description of consistency can be helpful. Does the patient complain of constipation? Physical examination should include gentle palpation of the abdomen for masses or distention. A careful rectal exam can identify the presence of stool in the rectum or a distended empty rectum. An empty, or “ballooned,” rectum may be a symptom of high obstruction. It is also difficult to distinguish stool from malignant mass. The ability to assess whether an impaction is low or high in the intestinal tract is important to help guide the intervention planning. As discussed above, lack of stool noted in the rectum during a digital exam is usually indicative of a high impaction. Stool has not or cannot move down into the rectum. The goal then would be to use careful assessment to be sure the obstruction is not a tumor and to concentrate on softening the stool and moving it through the GI tract. Again, using a stimulant laxative for this type of patient would result in increasing discomfort and possible rupture of the intestinal wall. Low impactions are uncomfortable, and patients may need more comforting measures. Patients may need to lie down to decrease pressure on the rectal area and avoid drinking hot liquids or eating big meals, which may increase peristalsis and discomfort until the impaction can be cleared.

**Radiological Examination**

Bowel obstruction may be diagnosed on the basis of a plain abdominal x-ray, but contrast may help identify the site and extent of the obstruction. Barium is not recommended because it may interfere with additional studies.

**Surgical Intervention**

A percentage of cancer patients may experience nonmalignant obstruction. Therefore, assuming the obstruction is related to worsening cancer may prevent the health care team from setting realistic treatment goals. A thorough assessment should be done, with attention to poor prognostic factors. These factors historically include general medical condition or poor nutritional status, ascites, palpable abdominal masses or distant metastases, previous radiation to the abdomen or pelvis, combination chemotherapy, and multiple small-bowel obstructions.

A study on the palliative benefit of surgery for bowel obstruction in advanced ovarian cancer found that surgical intervention provided successful palliation in 51% of the patients studied. Four prognostic factors for the probable success of palliative surgery were found: (1) absence of palpable abdominal or pelvic masses, (2) volume of ascites less than 3 liters, (3) unifocal obstruction, and (4) preoperative weight loss less than 9 kg. Sixty-eight percent of the patients survived longer than 60 days and recovered enough to be able to return home.

Surgical interventions can involve resection and reanastomosis, decompression, either colostomy or ileostomy, gastroenterostomy or ileotransverse colostomy, or lysis of adhesions. Prospective trials need to be done to further assess the success of surgical interventions and their effect on the quality as well as the quantity of life. Gastrostomy has been shown to be well tolerated for moderate to long-term decompression.

Surgical intervention should be a decision made between patient and physician within the established goals of care. The patient’s right to self-determination is essential. As patient advocates, our role is to educate the patient and family. Helping them to understand physician recommendations, as well as considering their personal desires and options in an effort to develop the treatment plan, is essential. Surgical resection for obstructing cancers of the GI tract, pancreatic, or biliary tracts was found to have a 3- to 7-month survival. This study pointed out the importance of nutritional status at baseline and assessment of performance status for its relationship to “reasonable quality of life.” The important conclusion of these studies was to leave the decision to operate with the patient. Mortality is possible. The need for additional surgeries remains high due to recurrence of the obstruction, wound infections, sepsis and further obstruction. Survival rates with each subsequent surgery lessen.

**Alternative Interventions**

Nasogastric or nasointestinal tubes have been used to decompress the bowel and/or stomach. Use of these interventions, although uncomfortable for the patient, has been suggested for symptom relief while evaluating the possibility of surgery. Venting gastrostomy or jejunostomy can be a relatively easy alternative, which is especially effective for severe nausea and vomiting. It can be placed percutaneously with sedation and local anesthesia. Patients can then be fed a liquid diet, with the tube clamped for as long as tolerated without nausea or vomiting.

**Symptom Therapy**

Providing aggressive pharmacological management of the distressing symptoms associated with malignant bowel obstruction (MBO) can prevent the need for surgical intervention. The symptoms of intestinal colic, vomiting, and diarrhea can be effectively controlled with medications for most patients. Depending on the location of the obstruction, either high or low, symptom severity can be affected. As accumulation of
secretions increases, abdominal pain also increases. Distention, vomiting, and prolonged constipation occur. With high obstruction, onset of vomiting is sooner and amounts are larger. Intermittent borborygmi and visible peristalsis may occur. Patients may experience colic pain on top of continuous pain from a growing mass. In chronic bowel obstruction, colic pain subsides.

As stated above, the goal of treatment is to prevent obstruction whenever possible. The use of subcutaneous (SQ) or intravenous (IV) analgesics, anticholinergic drugs, and antiemetic drugs can be effective for reducing the symptoms of inoperable and hard-to-manage obstruction. Octreotide may be an option in early management to prevent partial obstructions from becoming complete. Although octreotide is used for diarrhea because it decreases peristalsis, it also slows the irregular and ineffective peristaltic movements of obstruction, reducing the activity and balancing out the intestinal movement. It reduces vomiting because it inhibits the secretion of gastrin, secretin, vasoactive intestinal peptide, pancreatic polypeptide, insulin, and glucagon. Octreotide directly blocks the secretion of gastric acid, pepsin, pancreatic enzyme, bicarbonate, intestinal epithelial electrolytes, and water. It has been shown to be effective in 70% of patients for the control of vomiting. Octreotide is administered by SQ infusion or SQ injection every 12 hours. A negative aspect of this drug is its cost. It is expensive and requires SQ injections or IV infusions over days to weeks. The recommended starting dose is 0.3 mg/day and may increase to 0.6 mg/day. Hyoscine butylbromide is thought to be as effective as octreotide at reducing GI secretions and motility. Hyoscine butylbromide is less sedating since it is thought to cross the blood–brain barrier less due to its low lipid solubility. A recent study compared octreotide and scopolamine butylbromide for inoperable bowel obstruction with nasogastric tubes. Both medications relieve colicky pain; both reduce the continuous abdominal pain and distention. Although this was a small study done over 3 days, they were able to remove the nasogastric tube in three of the seven patients on the first dose of octreotide 0.3 mg/day subcutaneously; three more patients were able to have the nasogastric tube removed when the dose was doubled to 0.6 mg/day. Scopolamine was similar in results, but the octreotide regimen was felt to be overall more effective. The negative effect is associated with the cost of drug; a definite consideration for overall quality of life. Scopolamine is less expensive.

Analgesic Medications

Opioid medications have been used to relieve pain associated with obstruction. Providing the opioid through SQ or IV infusion via a patient-controlled analgesic (PCA) pump is beneficial for two reasons: patients may receive improved pain relief over the oral route due to improved absorption, and by giving access to a PCA pump, patients are allowed some control over their pain management. Alternative routes of opioid administration, such as rectal or transdermal, may also be effective but usually are inadequate if the pain is severe or unstable or there are frequent episodes of breakthrough pain.

Antiemetic Medications

Some antiemetic medications can also be given SQ and combined with an opioid. Haloperidol (Haldol) is the classic first-line antiemetic. Phenothiazine, butyrophenone, and antihistamine antiemetics are the most helpful. Recent additions of the selective serotonin antagonists, the 5-hydroxytryptamine blockers (5-HT3) have made a significant difference in the treatment of nausea, especially when combined with corticosteroids for chemotherapy-induced nausea (see also Chapter 9). Metoclopramide at 10 mg q 4 hours is the drug of choice for patients with incomplete bowel obstruction. It stimulates the stomach to empty its contents into the reservoir of the bowel. Once complete obstruction is present, metoclopramide is discontinued and haloperidol or another antiemetic medication is started. Haloperidol is less sedating than other antiemetic or antihistamine medications. The usual dose ranges from 5 to 15 mg/day, and at some institutions, it is combined with cyclizine. Corticosteroids are particularly helpful antiemetics, especially when related to chemotherapy. In practice, it is recommended that morphine, haloperidol, and hyoscine butylbromide be given together by continuous SQ infusion. If pain or colic increases, the dose of morphine and hyoscine butylbromide should be increased; if emesis increases, increase the haloperidol dose. Fluid and nutrient intake should be maintained as tolerated. Usually, patients whose vomiting has improved will tolerate fluids with small, low-residue meals. Dry mouth is managed with ice chips, although this has been suspected to wash out saliva that is present in the mouth. The use of artificial saliva may be more beneficial.

Corticosteroid Medications. Corticosteroids have been helpful as antiemetic medications. The recommended dose of dexamethasone is between 6 and 16 mg/day; the prednisolone dose starts at 50 mg/day (injection or SQ infusion). Twycross and Lack recommend starting with 4 mg bid for 5 days, then decreasing to 4 mg daily. One possible side effect to this medication is oral candidiasis.

Antispasmodic Medications

Colic pain results from increased peristalsis against the resistance of a mechanical obstruction. Analgesics alone may not be effective. Hyoscine butylbromide has been used to relieve spasm-like pain and to reduce emesis. Dosing starts at 60 mg/day and increases up to 380 mg/day given by SQ infusion. Side effects are related to the anticholinergic effects, including tachycardia, dry mouth, sedation, and hypotension.

Laxative Medications

Stimulant laxatives are contraindicated due to increased peristalsis against an obstruction. Stool-softening medications may be helpful if there is only a single obstruction in the colon or rectum. If the obstruction is in the small bowel, laxatives will not be of benefit.
Antidiarrheal Medications

Patients who experience a subacute obstruction or a fecal fistula may complain of diarrhea. Antidiarrheal medicine, such as codeine or loperamide, may be helpful. The benefit of these medications is that they may also help to relieve pain and colic. Octreotide may be helpful with bowel obstruction due to its mechanism of action. By inhibiting the release of certain secretions of the gastric, biliary, and intestine, intestinal motility decreases and increases absorption of water and electrolytes.33

Helping families cope with symptoms associated with obstruction is important. Historically, the management of obstruction involved aggressive surgical intervention or symptom management alone. The initial assessment should include: (1) evaluating constipation, (2) evaluating for surgery, (3) providing pain management, and (4) managing nausea with metoclopramide. If incomplete obstruction, use dexamethasone, haloperidol, dimenhydrinate, chlorpromazine, or hyoscine butylbromide.37 The introduction of new medications, such as octreotide, and newer antiemetics has made a difference in the quality of life a patient with a malignant bowel obstruction may experience. The important thing to remember is that the treatment plan must always be in agreement with the patient’s wishes. Discussing the patient’s understanding of the situation and the options available are essential to effective and thoughtful care of bowel obstruction in the palliative care patient.

ASCITES

Ascites associated with malignancy results from a combination of impaired fluid efflux and increased fluid influx.42 Ascites may be divided into three different types. Central ascites is the result of tumor-invading hepatic parenchyma, resulting in compression of the portal venous and/or the lymphatic system.44 There is a decrease in oncotic pressure as a result of limited protein intake and the catabolic state associated with cancer.44 Peripheral ascites is related to deposits of tumor cells found on the surface of the parietal or visceral peritoneum. The result is a mechanical interference with venous and/or lymphatic drainage.44 There is blockage at the level of the peritoneal space rather than the liver parenchyma. Macrophages increase capillary permeability and contribute to greater ascites. Mixed-type ascites is a combination of central and peripheral ascites. Therefore, there is both compression of the portal venous and lymphatic systems, as well as tumor cells in the peritoneum. Chylous malignant ascites occurs when tumor infiltration of the retroperitoneal space causes obstruction of lymph flow through the lymph nodes and/or the pancreas.44 Additional sources of ascites not related to malignancy include the following:

- Portal venous thrombosis
- Congestive heart failure
- Nephrotic syndrome
- Pancreatitis
- Tuberculosis
- Hepatic venous obstruction
- Bowel perforation

Severe ascites is associated with poor prognosis (40% 1-year survival, less than 10% 3-year survival).44 The pathological mechanisms of malignant ascites make the prevention or reduction of abdominal fluid accumulation difficult.45 Invasive management of ascites is seen as appropriate whenever possible, in contrast to intestinal obstruction. Although survival is limited, the effects of ascites on the patient’s quality of life warrant an aggressive approach.45

Tumor types most associated with ascites include ovarian, endometrial, breast, colon, gastric, and pancreatic cancers.34,45 Less common sources of ascites include mesothelioma, non-Hodgkin’s lymphoma, prostate cancer, multiple myeloma, and melanoma.44

Assessment of Ascites

Symptoms Associated with Ascites

Patients complain of abdominal bloating and pain. Initially, patients complain of feeling a need for larger-waisted clothing and notice an increase in belt size or weight. They may feel nauseated and have a decreased appetite. Many patients will complain of increased symptoms of reflux or heartburn. Pronounced ascites can cause dyspnea and orthopnea due to increased pressure on the diaphragm.44,45

Physical Examination

The physical examination may reveal abdominal or inguinal hernia, scrotal edema, and abdominal venous engorgement. Radiological findings show a hazy picture, with distended and separate loops of the bowel. There is a poor definition of the abdominal organs and loss of the psoas muscle shadows. Ultrason and computed tomographic scans may also be used to diagnose ascites.44

Management of Ascites

Traditionally, treatment of ascites is palliative due to decreased prognosis.44 Ovarian cancer is one of the few types where the presence of ascites does not necessarily correlate with a poor prognosis. In this case, survival rate can be improved through surgical intervention and adjuvant therapy.45
Medical Therapy

Advanced liver disease is associated with central ascites. There is an increase in renal sodium and water retention. Therefore, restricting sodium intake to 100 µmol/day or less along with fluid restriction for patients with moderate to severe hyponatremia (125 µmol/L) may be beneficial. Using potassium-sparing diuretics is also important. Spironolactone (is the drug of choice. Furosemide is also helpful at 60 mg/day to initiate diuresis. Over-diuresis must be avoided. Over-diuresis may precipitate electrolyte imbalance, hepatic encephalopathy, and prerenal failure. The above regimen of fluid and sodium reduction and diuretics may work for mixed-type ascites, which results from compression of vessels related to tumor and peripheral tumor cells of the parietal or visceral peritoneum as well. Because mixed-type ascites is associated with chylous fluid, adding changes to the diet, such as decreased fat intake and increased medium-chain triglycerides, may be important. Chylous ascites results from tumor infiltration of the retroperitoneal space, causing obstruction of lymphatic flow. Medium-chain triglyceride oil (Lipsorbs) can be used as a calorie source in these patients. Because the lymph system is bypassed, the shorter fatty acid chains are easier to digest. For patients with refractory ascites and a shortened life expectancy, paracentesis may be the most appropriate therapy.

Paracentesis for tense ascites associated with cirrhosis or nonmalignant ascites has been shown to shorten hospitalization by 60%. Multiple studies have found that removing 4 to 6 liters/day was a safe and effective treatment. This treatment has been altered to include albumin infusions, which prevent hypovolemia and renal impairment, as well as hyponatremia.

It is recommended that a maximum of 6 liters of ascites fluid be taken off. This can be a safe and effective way to promptly relieve patients of discomfort associated with ascites and to improve quality of life.

Peritoneovenous shunts (Denver or LeVeen shunt) are helpful for the removal of ascites in 75% to 85% of patients. These shunts are used primarily for nonmalignant ascites. The shunt removes fluid from the site, and the fluid is shunted up into the internal jugular vein.

Nursing Management

Ascites management involves initially understanding the mechanism, then using interventions appropriately. The reality of recurring ascites requiring repeated paracentesis is present. Acknowledging the risk/benefit ratio of repeated paracentesis is essential, especially in palliative care. Nurses need to remember good supportive care in addition to other resources. These include skin care, help prevent breakdown, and comfort interventions, such as pillow support, and loose clothing whenever possible. Educating the patient and caregivers on the rationale behind fluid and sodium restrictions when necessary can help their understanding and compliance. The cycle of a patient who feels thirsty, receives IV fluids, and has more discomfort is difficult for the patient to understand. Careful explanations about why an intervention is or is not recommended can go a long way toward improving the quality of life for these patients.

References

Advances in health care have changed the trajectory of dying and the way people die.

The last year of life for someone with a progressive debilitating disease is frequently associated with multiple distressing symptoms, comorbidities, and loss of independent function.

Difficulties with eating and drinking are common during this period.

Decisions regarding hydration and nutrition are confronted by patients, families, and staff at this time.

Discussions regarding artificial hydration and nutrition are frequently couched in terms of ethics, religious beliefs, and strongly held personal views.

Nurses need to know their state laws concerning provision of artificial hydration and nutrition in the dying patient.

Decisions regarding hydration and nutrition at end of life are guided by goals of care, benefit versus burden, and the wishes of the patient and family.

Patients have the right to refuse hydration and nutrition, whether parenteral or oral.

There is lack of consensus either in society or among experts as to whether it is physically, psychologically, socially, or ethically appropriate to provide artificial hydration and nutrition to a terminally ill person. Do these therapies improve the way an individual feels physically and emotionally? Do they cause harm? Can an individual die comfortably without these interventions? Decisions are usually made on the basis of whether the intervention will make the patient more comfortable and whether it will honor his or her wishes. These elements are illustrated in the following two case reports.

CASE STUDY

Two Patients Receiving Total Parenteral Nutrition

Mrs. S was a 70-year-old woman with advanced uterine cancer. She was a Holocaust survivor, as was her husband. Receiving and giving food were all-important to them both. Mrs. S was obstructed, had a draining percutaneous endoscopic gastrostomy tube, and was unable to take food by mouth. Total parenteral nutrition (TPN), which had originally been started as nutritional support during intensive chemotherapy, became an expression of nurturing and life in both their minds, when the focus of care became directed toward end-of-life care.

Although discontinuing chemotherapy had been a difficult transition for the patient and family, to discontinue TPN was inconceivable. This attitude continued until the end of life. The patient continued to receive TPN up until the time of her death. The deep-seated horror of living through the Holocaust and the deprivation of food they had experienced strongly affected this patient and her family’s unshakeable belief that food and water must be given until death.

A contrasting situation is illustrated through a man in his 40s, dying of gastric cancer, who had received TPN for nutritional support during chemotherapy. Administration of TPN had repeatedly been associated with increased pain. The patient had been willing to tolerate the increased pain when the goal of
HYDRATION

Water is an essential component of the human body. Complex cellular functions, such as protein synthesis and metabolism of nutrients, are affected by hydration status. The maintenance of hydration depends on a balance between intake and output, which is regulated by neuroendocrine influences. Homeostasis is maintained through parallel neuroendocrine activity on excretion of fluid via the kidneys and on intake via thirst. Increased osmotic pressure is the prime stimulus for thirst, stimulating the release of vasopressin. Renal excretion is mainly dependent on the action of vasopressin, which is secreted by the posterior pituitary gland. This hormone, known as antidiuretic hormone (ADH), increases water reabsorption in the collecting ducts of the kidneys. Thirst stimuli include hypertonicity; depletion of the extracellular fluid compartment arising from vomiting, diarrhea, or hemorrhage; and renal failure, in which plasma sodium is low but plasma renin levels are high.

Dehydration is a loss of normal body water. There are several types of dehydration. Isotonic dehydration results from a balanced loss of water and sodium. This occurs during a complete fast and during episodes of vomiting and diarrhea with the loss of water and electrolytes in the gastric contents. Billings theorized that terminally ill individuals have this type of balanced decrease in food and fluid intake, causing eunatremic dehydration (sodium levels in normal range) because of the simultaneous loss of salt and water. Hypertonic dehydration occurs if water losses are greater than sodium losses. Fever can cause this problem, by loss of water through the lungs and skin and a limited ability to take in oral fluids. Hypotonic dehydration occurs when sodium loss exceeds water loss. This typically occurs when water is consumed but food is not. Overuse of diuretics is a major factor. Osmotic diuresis (e.g., from hyperglycemia), salt-wasting renal conditions, third spacing (ascites), and adrenal insufficiency are other common causes of sodium loss.

The methodology for assessing dehydration has not been well studied and tends to vary among practitioners. The clinical sensitivity of each method has not been determined. Clinical assessment should include mental status changes, thirst, oral/parenteral intake, urine output, and fluid loss. Physical findings, weight loss, dry mouth, dry tongue, reduced skin turgor, and postural hypotension should be noted. Laboratory test findings, including increased hematocrit, elevated serum sodium concentration, azotemia with a disproportionate rise in blood urea nitrogen in relation to creatinine, concentrated urine, and hyperosmolarity, are indicative of dehydration.

Physical findings (Table 12–1) are complicated to evaluate. Comorbid conditions can be the cause of many of these symptoms in the chronically or terminally ill individual. Dry mouth, for example, can be associated with mouth breathing or anticholinergic medication. Skin turgor can be hard to evaluate in the cachexic individual and is unreliable. Obtaining weights may be impractical, but rapid weight loss of greater than 3% is indicative of dehydration. Postural hypotension can be related to medications and cardiac pathology. Confusion is common in the patient with advanced cancer and may have many causes, including the disease state itself. Thirst may be absent or mild in patients with hyponatremic dehydration, although marked volume loss may stimulate ADH and water craving.

There is evidence that elderly individuals do not perceive thirst in the same manner as healthy young adults. In a study comparing the role of thirst sensation and drinking behavior in young versus older adults, water was restricted for 24 hours. Only the young, healthy study group reported a dry, unpleasant mouth and a general sense of thirst; the healthy elders had a deficit in the awareness of thirst despite plasma osmolality and sodium and vasopressin concentrations that were greater than those in the younger group. During the rehydration period, the younger group consumed enough fluid to correct their laboratory values. Elder subjects did not consume enough fluid to correct the laboratory values. There is not, however, any evidence to support this observation in terminally ill patients. In hypernatremia, thirst is a powerful stimulus, and persons with access to water usually will take in sufficient amounts of fluid. Confused or somnolent individuals and those who are unable to drink are at risk because water losses may not be adequately replaced. Dehydrated, terminally ill patients usually present with mixed disorders of fluid and salt loss.

Dehydration causes confusion and restlessness in patients with nonterminal disease. These same symptoms are frequently reported in terminally ill persons and could be aggravated by dehydration. Reduced intravascular volume caused
by dehydration can result in renal failure. Opioid metabolite accumulation can result from renal failure and cause confusion, myoclonus, and seizures. Dehydration has been associated with an increased risk of bedsores and constipation, particularly in the elderly. Discomfort, especially problems with xerostomia and thirst, may result from dehydration.11

Dehydration may improve physical caregiving for some patients. For example, urinary catheters may be avoided if the frequency of urination decreases. With dehydration, there is less gastrointestinal fluid, with fewer bouts of vomiting, and a reduction in pulmonary secretions, with less coughing, choking, and need for suctioning. Some palliative care clinicians suggest that dehydration at the end of life causes suffering in some patients, which should be relieved. This suffering may include thirst, dry mouth, fatigue, nausea, vomiting, confusion, muscle cramps, and perhaps the hastening of death.12,13

Dehydration as a cause of renal failure has been well documented.14,15 A study of terminally ill cancer patients, however, showed that the group receiving intravenous fluids at a rate of 1 to 2 L/day consistently had more abnormal laboratory values of serum sodium, urea, and osmolarity than the group who were not hydrated.16

The researchers concluded that artificial hydration to alleviate symptoms may be futile. These results contrast with those of a study of 100 palliative care patients receiving hypodermoclysis; researchers in the latter investigation concluded that this therapy was useful for achieving better symptom control.18 An anecdotal study of three patients being hydrated by hypodermoclysis reported that hydration may have contributed to improved cognitive function and allowed patients to deal with end-of-life issues.19

Some experts suggest that hydration may relieve symptoms other than thirst, such as confusion and restlessness.14 Still others who have looked at the issue of dehydration-related suffering have stressed the role of inappropriate medical interventions that cause their own problems. They contend that hydrating a patient can be associated with repetitive needlesticks, decreased mobility, increased secretions, increased edema, and possibly congestive heart failure.20,21 It is also suggested that improving the cognition of a dying patient with pain may make the patient more aware of the pain, with the

The possibility of decreasing cognition once more through increased opioid requirements. Others state that comatose patients feel no symptoms; fluids may prolong dying, and dehydration may act as an anesthetic.\textsuperscript{14}

In a descriptive study of symptoms of dehydration in the terminally ill, no association was found between fluid intake, serum sodium, osmolality, blood urea nitrogen, and symptom severity.\textsuperscript{12} A survey of Swiss physicians found that there was no consensus with respect to the assessment of “suffering” from dehydration or thirst. The physicians who chose artificial hydration were more likely to perceive suffering and thirst as serious problems. Two thirds of the doctors did not believe that artificial hydration was the best way to respond to terminal dehydration.\textsuperscript{22}

The decision to use artificial means of hydration comes more from tradition than from science. To avoid unnecessary interventions in the course of the dying process, some practitioners have avoided artificial fluid replacement secondary to its perceived negative effects. Their conclusion, that artificial hydration may cause harm to some dying patients, keeps them from offering this therapy. Palliative care clinicians have noted that some individuals are more comfortable without artificial fluids, which may prolong the dying process, whereas others are more comfortable when artificial hydration is used. Emotional issues are often the driving force in the decision to provide or withdraw artificial hydration. The need to provide fluids may be directed by very strong cultural, religious, and/or moral convictions on the part of patients, families, and some caregivers even if there is no certainty that the therapy does provide comfort.

**Screening for Dehydration, Management, and Assessing the Effects of Interventions**

Screening for dehydration in the palliative care setting may include recording intake and output, examining skin turgor and mucous membranes, and monitoring mental status and blood pressure. Subjective reports of fatigue, muscle weakness, anorexia, and taste alteration are correlated with these signs and laboratory values (see Table 12–1). The benefits and possible adverse effects of hydration should be discussed within a broad framework of goals of care and the wishes of the patient and family explored within that framework. Each situation has unique aspects that affect choices and the outcome of therapy. Finally, there is a need for regular reassessment to allow for changes in therapy and frequent discussions with patients and families to provide opportunities to reevaluate decisions.

The treatment of dehydration starts with a review of medications and elimination, if possible, of any agents (diuretics) that may be contributing to the dehydration. Mouth care should be provided regularly. Intervening or treating dehydration may include various routes of administration. A standard goal for fluid intake is 1500 to 3000 mL, or 8 to 10 glasses, of water daily.\textsuperscript{7} The least invasive approach to replacing fluids is to offer liquid orally at regular intervals. For those able to swallow, this approach can help the patient as well as promote the emotional well-being of the caregivers. Those who are very weak, depressed, confused, agitated, or demented may need significant assistance in getting the fluids in on a regular basis.

The benefit/burden ratio for the patient in aggressively pursuing such a fluid intake approach must be carefully weighed. Care must be taken to avoid overhydration by a well-meaning but misdirected aggressive approach, and the patient should be monitored for new orthopnea, shortness of breath, increased emotional distress, or change in mental status. If the ability to swallow is diminished, there is a risk of aspiration and causing more distress to the patient. Small, frequent sips of fluid or ice chips can be provided. Choice of fluids should be patient driven. Some individuals find sports replacement fluids a good choice because they are easily absorbed by the stomach and can correct hypertonic dehydration.\textsuperscript{5} Use of a fine mist spray can also help to keep mucous membranes moist.\textsuperscript{22} Hot, humid weather conditions can add to the risk of dehydration, so the use of air conditioning and fans should be considered.

**Alternative Routes of Hydration When the Oral Route Is No Longer Reliable**

If there are days or weeks of life expected, and if it is appropriate to the goals of care and wishes of the patient and family, a more reliable route of fluid replacement may be chosen. Rehydration by *proctoclysis* is relatively risk-free and less expensive than parenteral means of administration.\textsuperscript{24} Through a nasogastric tube placed rectally, tap water or saline is instilled, starting at about 100 mL/h. If there is no discomfort, leakage, or tenesmus (spasm of the anal sphincter), the rate can be increased to 400 mL/h. One liter of fluid can be instilled over 6 to 8 hours. Care must be taken, however, not to overhydrate. Side effects of this route of hydration can include pain, edema, rectal leakage of fluid, and pain during insertion of the tube. Researchers report that although proctoclysis is effective, safe, and economical, most patients prefer hypodermoclysis.\textsuperscript{24} It is possible to foresee cultural and social reluctance to accept the rectal mode of fluid administration. In an inpatient setting, clinical staff would administer the fluids, but in a home setting, it may be impractical to use professional staff daily for this treatment. Family caregivers or patients may be uncomfortable with relatives or friends having to assume this type of care.

Standard methods for replacement of fluids can be achieved by the use of enteral feeding tubes and by parenteral methods, such as subcutaneously (hypodermoclysis) or intravenously. A feeding tube placed through the nose is often uncomfortable and may agitate the confused individual. Patients often extubate themselves when agitated. Endoscopic gastrostomy tubes have become more popular but are usually placed for decompression or feeding rather than for fluid replacement. If the individual has a feeding tube or a permanent intravenous access device (port or peripherally inserted central catheter), these may be used safely without any added burden for the patient. Placement of these devices, however, needs to be considered in the context of the overall goals of therapy.
Hypodermoclysis (subcutaneous fluid administration) does not require special access devices. This method has the advantage over the intravenous route in people who have poor venous access. Use of this method may prevent transfer to an acute setting for line placement. Hypodermoclysis can also be initiated in the patient’s home. It does not require monitoring for clotting in the line, and there is no fear of letting the line “run dry.” There can be local irritation at the site of infusion, however, as well as minor bleeding. Sloughing of tissue is possible with over-infusion, and abscess formation may occur (Table 12–2). Hypotonic or isotonic solutions, with or without hyaluronidase or corticosteroids, are administered through needles inserted into the subcutaneous tissue of the abdomen or anterior or lateral thigh. Most individuals can tolerate 100 mL/h or more. Up to 1500 mL can be administered into a single site.8,25 The following case report illustrates the use of hypodermoclysis.

**Case Study**

Mr. G, a 55-Year-Old Man with Colon Cancer

Mr. G was a 55-year-old man with advanced colon cancer. He was obstructed and unable to take oral food or water. His goal was to remain alert and interactive with his wife and children for as long as possible. Enteral feedings were not feasible, and venous access for fluids was complicated by recurrent port and line infections. Maintaining hydration, however, was felt to be important for achieving the patient’s goals. Because of the complications associated with his venous access, hypodermoclysis was chosen as the most appropriate route for fluid administration. Subcutaneous fluids at 100 mL/h were continued for the last 4 months of his life. This subcutaneous access also provided a parenteral route for opioid administration. Mr. G remained alert and interactive up until the last day of life. In this case, hypodermoclysis appeared to have been an appropriate use of technology and hydration in end-of-life care.

Replacement of fluids by the intravenous route is more technically complicated, and access to a competent vein must be available. Some patients have permanent-access devices, placed for therapy earlier in their treatment, that are more than adequate for this type of administration. Others may wish to have a device placed. Use of a regular intravenous line for ongoing hydration at home can be hard to maintain; if ongoing parenteral fluids are required, placement of a central catheter or peripherally inserted central catheter (PICC) line is the norm in these situations. Small, portable pumps to regulate fluid flow are available for hydration of a patient in the inpatient or home setting. Some individuals choose to run fluids via the permanent-access devices only at night. This allows for more mobility during the daylight hours. There needs to be a competent caregiver to monitor the therapy, and because caregivers accept many duties, this can be overwhelming to some.

Consensus on the appropriate volume or type of fluid replacement does not exist. Clinicians make choices based on their previous experience and knowledge of the patient’s condition and wishes. Some practitioners allow the individual to have 1 L/day despite the fact that it is inadequate replacement. Considerations also include safety and reality of the care burden on all caregivers. Providing 1 L of fluid per day may only partially correct the patient’s deficits, but it may relieve the emotional burden of needing to provide fluids. Administration of 1 L/day can often be worked into the patient’s and family’s schedule better. If fluids are given only at night, the patient may be more mobile during the day. Fluid administration can be scheduled to accommodate the goals of living. More aggressive fluid replacement requires monitoring of serum electrolytes and blood counts by regular laboratory testing. This type of approach requires monitoring of laboratory results and making adjustments every 24 to 48 hours.

Patients and family members can be taught to manage hydration techniques at home. An assessment of their concerns should precede the instruction about the actual procedures.

IV, intravenous; SC, subcutaneous

Hypodermoclysis (subcutaneous fluid administration) does not require special access devices. This method has the advantage over the intravenous route in people who have poor venous access. Use of this method may prevent transfer to an acute setting for line placement. Hypodermoclysis can also be initiated in the patient’s home. It does not require monitoring for clotting in the line, and there is no fear of letting the line “run dry.” There can be local irritation at the site of infusion, however, as well as minor bleeding. Sloughing of tissue is possible with over-infusion, and abscess formation may occur (Table 12–2). Hypotonic or isotonic solutions, with or without hyaluronidase or corticosteroids, are administered through needles inserted into the subcutaneous tissue of the abdomen or anterior or lateral thigh. Most individuals can tolerate 100 mL/h or more. Up to 1500 mL can be administered into a single site.8,25 The following case report illustrates the use of hypodermoclysis.
Adequate time must be allowed for education and return demonstration. Backup support should be provided, and repetitive sessions may be required. If possible, direct instruction to more than one caregiver should be provided, to allow them to help each other with the tasks required. Printed materials that are age and reading level appropriate should be given. In addition, video instructions can be helpful, if they are available. Follow-up visits or calls should be scheduled to assess level of functioning, to give support, and to reinforce teaching. These therapies may mean more home visits, to accommodate those who learn more slowly or are not able to master all or part of the procedure. Specific protocols vary among institutions and agencies; however, written policies and procedures should guide practice.

Dry Mouth and Thirst

Other symptoms related to dehydration can be assessed and treated. Thirst can be relieved by small amounts of fluid offered frequently. Dry mouth is treated with an intensive every-2-hour schedule of mouth care, including hygiene, lip lubrication, and ice chips or popsicles. Elimination of medications that cause dry mouth, such as tricyclic antidepressants and antihistamines, should be considered. Usually, however, the drugs that contribute to these symptoms are being administered to palliate other symptoms. Mouth breathing can also cause dry mouth. Candida infection, a frequent cause of dry mouth in the debilitated individual, can be treated. Agents such as pilocarpine (Salagen) can be used to increase salivation.

Table 12–3
Hydration and Nutrition in the Terminally Ill: Guiding Principles of Ethical Decision Making

- Everything in the terminal phase of an irreversible illness should be decided on the basis of whether it will make the patient more comfortable and whether it will honor his or her wishes.
- Treatments are evaluated principally according to their consequences—benefits and burdens, physical, psychosocial, and spiritual—weighed within the patient's value framework.
- Dehydration per se does not require treatment, but symptoms associated with dehydration do require palliation.
- When a patient is unable to express his or her wishes, advance directives or input from the health care proxy is followed.
- Although the focus is the patient, attention to the concerns and distress of the family is essential.

Whether or Not to Provide Artificial Hydration at End of Life

Controversy about providing hydration for terminally ill individuals stems from trying to balance the medical tradition of doing everything possible to heal and prolong life with the idea of allowing patients to die comfortably without unnecessary interventions. Empirical studies of clinical practice suggest that the setting of end-of-life care influences the use of artificial hydration at the end of life. Patients are more likely to receive hydration if they are cared for in an acute care setting and are less likely to receive hydration if they are cared for in a hospice program.26–30

What is the role of medical intervention at the final stage of illness? In conventional medical management, dehydration is routinely avoided or reversed with fluid and electrolyte replacement. Similarly, whenever a terminal ill patient seeks to prolong life, and if the goal of care is to prolong life, maintaining hydration is accepted medical management. Conversely, if a terminally ill patient does not wish to delay death or even seeks to hasten dying, fluid replacement is generally inappropriate. Table 12–3 outlines the principles of ethical decision-making in regard to artificial hydration and nutrition in the terminally ill. Table 12–4 illustrates four clinical scenarios or paradigm cases that the nurse may encounter while caring for the terminally ill and that influence clinical decision-making.

Dehydration may aggravate or alleviate the discomfort of terminal disease (Table 12–5).6 Current research does not clearly guide practice. Dehydration causes unpleasant symptoms, such

| Paradigm case 1 | The dying patient who becomes too weak or too obtunded to maintain normal fluid intake, who will die soon but may die less comfortably and perhaps more quickly without rehydration. |
| Paradigm case 2 | The terminally ill cancer patient who has an inoperable intestinal obstruction, feels hungry, and wants to be fed. |
| Paradigm case 3 | The terminally ill patient whose inability to take oral food or fluid is precipitated by, or partially the result of, palliative medical management; for example, the patient who is sedated in an attempt to manage a refractory symptom such as pain, dyspnea, or agitated delirium. |
| Paradigm case 4 | The dying patient who voluntarily stops eating and drinking in order to hasten death. |
as confusion and restlessness, in nonterminally ill patients. These problems are common in the dying. Dehydration can cause renal failure with an accompanying accumulation of opioid metabolites, which causes further symptoms, such as myoclonus and even seizures. Dehydration is also associated with constipation and increased risk of bedsores. Clinicians report that these symptoms are mild and easily treated without hydration and that some symptoms, such as increased secretions, are actually made worse by rehydration.6,12,20 Hospice nurses have reported that the dehydrated patient is not uncomfortable.31,32 There is concern that artificial hydration diminishes quality of life by adding tubes, which create a physical barrier that separates the terminally ill from their loved ones. There is often fear that hydration unnecessarily prolongs dying. Patients and families may be making decisions based on inadequate knowledge or misconceptions about artificial hydration, such as the idea that it is helpful at any stage of disease or that it can increase strength.31

Those clinicians who support the use of hydration point to the prevention or relief of some symptoms, such as delirium.13,16 Because food and fluids are viewed by many as a symbol of life, not to maintain fluids or to withdraw artificial hydration at the end of life may cause spiritual or emotional conflict. These issues are complex and involve not only physical, psychological, and social concerns but also individual ethical dilemmas.

NUTRITION

To observe an anorexic, fatigued, wasted, and debilitated patient is disheartening for the family. Food is more than nutrition; it plays an important role in maintaining hope. For those who are able to enjoy eating, every opportunity to offer nourishment should be taken. However, attempts at aggressive nutritional intervention for someone who is unable to eat may end up being frustrating for the family and add to the patient’s suffering.33

Malnutrition is a common problem in patients with chronic, advanced debilitating illnesses such as acquired immunodeficiency syndrome (AIDS) or cancer. Anorexia, a loss of appetite, occurs in most patients during the last weeks of life. Cancer cachexia is a complex syndrome characterized by loss of appetite, generalized tissue wasting, skeletal muscle atrophy, immune dysfunction, and a variety of metabolic alterations.35,36 It is likely that asthenia, mental and physical fatigue coupled with generalized weakness, is directly related to malnutrition.37–39
Administration of nutrition in the terminally ill is sometimes proposed as a medical intervention for nutrition-related symptoms or management of side effects such as weight loss, weakness, constipation, pressure sores, intestinal obstruction, and dehydration. Nutritional intervention is also recommended to prevent further morbidity and maintain quality of life by controlling blood sugars or electrolyte imbalance. Lastly, nutritional therapy is offered to provide enough dietary intake to maintain energy.

Enteral and parenteral feedings are, however, interventions with the potential for associated morbidity and increased suffering (Table 12-6). The American Medical Directors Association (AMDA), a group that represents nursing home physicians, has published a white paper including a section that cautions against tube feeding in patients with advanced dementia unless they have clearly indicated their desire for such treatment. This group believes that there is no advantage to tube feeding and that less time is spent and fewer complications are encountered with hand feeding.40 Until the literature is conclusive, the clinician must stay current with the research in this area.41

Anorexia is influenced by alterations in taste, alterations in the gastrointestinal system, changes in metabolism, and effects of the tumor itself. In addition, psychological factors such as depression or anxiety can change eating habits. Pain, fatigue, and nausea may also decrease the desire for oral intake. Many aspects of the cancer experience decrease caloric intake. Taste changes may result from the tumor itself or from various treatments such as chemotherapy, surgery, radiation, or antibiotics.42 These taste changes may in turn decrease digestive enzymes and delay digestion.43 The gastrointestinal tract may be altered by tumor, opportunistic infections such as Candida, or ulcerations resulting from chemotherapy or radiation that cause diarrhea. These alterations can interfere with ingestion, digestion, and absorption. Nausea and vomiting may ensue. Abnormalities in glucose metabolism, increases in circulating amino acids or lactic acid, and increases in free fatty acids can cause early satiety.44 Increased blood sugar and serotonin levels in the brain may also decrease appetite.45 In addition, cytokines such as interleukin-1 and tumor necrosis factor, released from tumors, may mediate anorexia and decrease gastric emptying.46

The patient with advanced chronic illness may have increased caloric needs due to changes in metabolism. The basal metabolic rate can be increased by infection or malignancy. Age, nutritional status, temperature, hormones, and trauma can also change the metabolic rate. Unlike healthy persons, these patients have no adaptation to a decrease in food intake; metabolism does not slow down. Cytokines increase resting energy expenditure and skeletal muscle wasting.46 Nutrients that help to maintain immune function are decreased, and the resulting immunosuppression increases the risk of infection. Tumors invading the esophagus, stomach, or bowel can cause compression or obstruction and may limit oral intake. Surgery to remove tumors can remove all or part of the organs that produce digestive enzymes. This results in incomplete digestion. A shortened intestine reduces the number of villi available for absorption of nutrients.44

Nutritional Assessment

Within the framework of goals of care, disease status, and closeness to death, nutritional assessment starts with a diet history. The history should include the individual’s usual dietary habits, current eating habits, and disease symptoms. Food preferences and aversions should be explored, as well as family support and the ability to obtain and prepare foods. The educational needs of the patient and of caregivers should also be assessed. A food diary may be helpful in this situation, and dietitians recommend a 72-hour history followed by weekly documentation. A physical examination to screen for changes in oral mucosa and dentition should be performed.

Anthropometric measurements are part of nutritional assessment. These are often limited in scope at the end stages of disease. A history of weight loss of 20% or greater is indicative of increased morbidity and mortality.47 In the patient with advanced disease, weight gain may indicate the presence of...
edema or ascites, and weight loss may indicate dehydration. Other anthropometric measurements, such as skinfold thickness and midarm circumference, assess muscle and fat stores and can be used to monitor progress. Laboratory values are also used to estimate protein stores. These biochemical measurements are the mainstay for determining TPN. The appropriateness of each of these assessment parameters is determined on a case-by-case basis in the terminally ill.

Nutritional therapy is aimed at improving intake and managing cachexia. Increasing appetite is sometimes possible with pharmacological therapy. Steroids have been known to increase appetite, but their long-term use can cause muscle weakness. High-dose megestrol acetate has been shown to increase appetite with subsequent weight gain. Metoclopramide, tetrahydrocannabinol, and insulin have resulted in some improvement, but toxicities were problematic and the data were often insufficient. Exercise has been shown to stimulate appetite; however, few end-stage patients are able to participate in the type of exercise that is necessary to increase appetite.

Nursing measures to promote oral intake include managing other symptoms (e.g., constipation, pain, nausea) that negatively affect appetite. In addition, patients may require more seasoning than usual for food to taste good. Good oral care and unhurried meals should be encouraged. Suggesting that the patient allow others to cook may preserve energy for eating as well as decrease the negative effects of food odors. Wine or beer has been known to stimulate appetite but may be poorly tolerated by terminally ill patients or those receiving multiple medications with sedating properties.

Enteral feedings use the gastrointestinal tract for delivery of nutrients, and oral supplementation of nutrients can be tried in individuals who have the capacity to swallow. Care must be taken, however, to monitor the use of these supplements. Caregivers and patients sometimes feel a moral obligation to provide food and “push” the supplements at the risk of harm. 50,51 Metoclopramide, tetrahydrocannabinol, and insulin have resulted in some improvement, but toxicities were problematic and the data were often insufficient. Exercise has been shown to stimulate appetite; however, few end-stage patients are able to participate in the type of exercise that is necessary to increase appetite.

Summary

We inherit beliefs that govern our behavior. Among them are numerous contradictory notions that associate support with sustenance. Attitudes, preferences, and decisions may be influenced by race, gender, and culture. 52 The rites of family meals and celebrations provide bonding and sharing as well as food—fundamental components of personal and social life. The issues of hydration and nutrition at the end of life are complex and require a thoughtful, individualized approach. 53,54 Nurses and physicians are guided to institute or withdraw artificial nutrition or hydration based on the ethical principles of autonomy, beneficence and nonmaleficence. 55,56 Provision of accurate and complete information by the nurse can influence a patient’s and family’s decisions about these matters. 57

References

Dyspnea is a very common symptom in people with advanced disease and can severely impair their quality of life. The presence of dyspnea correlates with the probability of dying in hospital. In one international study, dyspnea prompted the use of terminal sedation in 25% to 53% of patients. Management of breathlessness requires understanding and assessment of the multidimensional components of the symptom, knowledge of the pathophysiological mechanisms and clinical syndromes that are common in people with advanced disease, and knowledge of the indications and limitations of the available therapeutic approaches.

**Definition**

The American Thoracic Society has defined *dyspnea* as the "term used to characterize a subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity." Dyspnea, like pain, is multidimensional in nature, with not only physical elements but also affective components, which are shaped by previous experience. The neuropathways responsible for the sensation of dyspnea are poorly understood, and no single physiological mechanism or unique peripheral site can explain the varied circumstances that lead to the perception of breathlessness. Stimulation of a number of different receptors (Figure 13–1) and the conscious perception this stimulation invokes can alter ventilation and result in a sensation of breathlessness.

**Prevalence and Impact**

The prevalence of the dyspnea varies according to the stage and type of underlying disease. Approximately 50% of a general outpatient cancer population describe some breathlessness, with this number rising to as much as 70% in the terminal phases of...
The prevalence of dyspnea is even more common in patients with lung cancer; almost 90% of them complain of breathlessness just before death. In a study of patients with end-stage chronic obstructive pulmonary disease (COPD), extreme breathlessness was experienced by 95% of the participants and was the most distressing and debilitating symptom. Dyspnea is also quite prevalent in the last year of life of people with congestive heart failure (CHF): 61% of these patients experience dyspnea, 72% of them having dyspnea for ≥6 months. Likewise, dyspnea occurs in 37% of patients with cerebrovascular accident (of whom 57% were breathless for ≥6 months); in 47% to 50% of patients with amyotrophic lateral sclerosis (ALS); and in 70% of those with dementia.

In a study of late-stage cancer patients, Roberts and associates used patient self-report surveys, chart audits of patients under the care of a hospice program, and interviews of patients and nurses in a home-care hospice program to examine the occurrence of dyspnea during the last weeks of life. They found that 62% of the patients with dyspnea had been short of breath for ≥3 months. Various activities intensified dyspnea for these patients: climbing stairs, 95.6%; walking slowly, 47.8%; getting dressed, 52.2%; talking or eating, 56.5%; and at rest, 26.1%. The patients universally responded by decreasing their activity to whatever degree would relieve their shortness of breath. Most of the patients had received no direct medical or nursing assistance with their dyspnea, leaving them to cope in isolation. Brown and colleagues found that 97% of lung cancer patients had socially isolated themselves from friends and outside contacts to cope with their dyspnea. Studies in patients with COPD, CVA, or end-stage heart or neurological diseases have also demonstrated the presence of significant dyspnea and other symptoms, functional disability, and impaired quality of life in the last year of their lives.

Patients with advanced disease typically experience chronic shortness of breath with intermittent acute episodes. Acute attacks of breathlessness are usually accompanied by feelings of anxiety, fear, panic, and, if severe enough, a sensation of impending death. Patients and family members who were participants in a qualitative study using narrative analysis consistently expressed fear of dying during a future acute episode of breathlessness, or of watching helplessly as a loved one became increasingly breathless and died before receiving any help. Many dying persons are terrified of waking in the middle of the night with intense air hunger. They need providers who will anticipate their fears and provide symptomatic relief of their breathlessness and anxiety as they approach death.

Pathophysiology

Management of dyspnea of patients requires an understanding of its multidimensional nature and the pathophysiologic mechanisms that cause this distressing symptom. Exertional dyspnea in cardiopulmonary disease is caused by (1) increased ventilatory demand, (2) impaired mechanical responses, or (3) a combination of the two. The effects of abnormalities of these mechanisms can also be additive.
Increased Ventilatory Demand

Ventilatory demand is increased because of increased physiological dead space resulting from reduction in the vascular bed (from thromboemboli, tumor emboli, vascular obstruction, radiation, chemotherapy toxicity, or concomitant emphysema); hypoxemia and severe deconditioning with early metabolic acidosis (with excessive hydrogen ion stimulation); alterations in carbon dioxide output ($V_{\text{CO}}_2$) or in the arterial partial pressure of carbon dioxide ($P_{\text{CO}}_2$) set point; and non-metabolic sources, such as increased neural reflex activity, or psychological factors such as anxiety and depression.

Impaired Mechanical Response/Ventilatory Pump Impairment

Impaired mechanical responses result in restrictive ventilatory deficits due to inspiratory muscle weakness, pleural or parenchymal disease, or reduced chest wall compliance; airway obstruction from coexistent asthma or COPD, or tumor obstruction. Patients may also have a mixed obstructive and restrictive disorder.

Multidimensional Assessment of Dyspnea

Dyspnea, like pain, is a subjective experience that may not be evident to an observer. Tachypnea, a rapid respiratory rate, is not dyspnea. Medical personnel must learn to ask and accept the patient’s assessments, often without measurable physical correlates. If patients say they are having discomfort with breathing, we must believe that they are dyspneic.

To determine whether dyspnea is present, it is important to ask more than the question, “Are you short of breath?” Patients often respond in the negative to this simple question because they have limited their activities so they won’t become short of breath. It is therefore helpful to ask about shortness of breath in relationship to activities: “Do you get short of breath walking at the same speed as someone of your age?” “Do you have to stop to catch your breath when walking upstairs?” “Do you get short of breath when you are eating?”

Qualitative Aspects of Dyspnea

Dyspnea is not a single sensation. Recent work suggests that the sensation of breathlessness encompasses several qualities. Just as the descriptions “burning” or “numb” suggest neuropathic pain, phrases such as “chest tightness,” “exhalation,” and “deep” were among a cluster of words associated with asthma. It is possible that dyspnea mediated by similar receptors evokes common word descriptors. From the research to date, it is not known whether qualitative assessments of dyspnea in breathless patients permit any discrimination among the various cardiopulmonary disorders. O’Donnell and coworkers found that, although descriptor choices were clearly different between health and disease states, they provided no discrimination among various diseases (e.g., COPD, restrictive lung disease, and CHF). Others have suggested that changes in the quality of dyspnea may prompt patients with heart failure to go to the emergency department.

Clinical Assessment

Clinical assessments are usually directed at determining the underlying pathophysiology, to decide appropriate treatment, and at evaluating the response to therapy.

The clinical assessment of dyspnea should include a complete history of the symptom, including its temporal onset (acute or chronic), whether it is affected by positioning, its
qualities, associated symptoms, precipitation and relieving events or activities, and response to medications. A past history of smoking, underlying lung or cardiac disease, concurrent medical conditions, allergy history, and details of previous medications or treatments should be elicited.32,33

Careful physical examination focused on possible underlying causes of dyspnea should be performed. Particular attention should be directed at signs associated with certain clinical syndromes that are common causes of dyspnea. Examples are the dullness to percussion, decreased tactile fremitus, and absent breath sounds associated with a pleural effusion in a person with lung cancer; an elevated jugular venous pressure (JVP), audible third heart sound (S3), and bilateral crackles audible on chest examination associated with CHF; and elevated JVP, distant heart sounds, and pulsus paradoxus in people with pericardial effusions.32,33

Gift and colleagues34 studied the physiological factors related to dyspnea in subjects with COPD and high, medium, and low levels of breathlessness. There were no significant differences in respiratory rate, depth of respiration, or peak expiratory flow rates at the three levels of dyspnea. There was, however, a significant difference in the use of accessory muscles between patients with high and low levels of dyspnea, suggesting that this is a physical finding that reflects the intensity of dyspnea.

Diagnostic tests helpful in determining the cause of dyspnea include chest radiography; electrocardiography; pulmonary function tests; arterial blood gases; complete blood counts; serum potassium, magnesium, and phosphate levels; cardiopulmonary exercise testing; and tests specific for suspected underlying pathologies, such as an echocardiogram for suspected pericardial effusion.35 The choice of appropriate diagnostic tests should be guided by the stage of disease, the prognosis, the risk/benefit ratios of any proposed tests or interventions, and the desires of the patient and family.

Nguyen and colleagues36 found that the ratings of intensity of dyspnea during laboratory exercise, clinical measures of dyspnea such as the Oxygen Cost Diagram, and pulmonary function tests captured distinctly different information in patients with moderate to severe COPD. It is therefore not surprising that results of pulmonary function tests do not necessarily reflect the intensity of a person’s dyspnea. Individuals with comparable degrees of functional lung impairment may also experience considerable differences in the intensity of dyspnea they perceive.4 Factors such as adaptation, differing physical characteristics, and psychological conditions can modulate both the quality and the intensity of the person’s perception of breathlessness.

The Visual Analog Scale (VAS) is one of the most popular techniques for measuring the perceived intensity of dyspnea. This scale is usually a 100-mm vertical or horizontal line, anchored at each end by words such as “Not at all breathless” and “Very breathless.” Subjects are asked to mark the line at the point that best describes the intensity of their breathlessness. The scales can be used as an initial assessment, to monitor progress, and to evaluate effectiveness of treatment in an individual patient.36

The modified Borg scale is a scale with nonlinear spacing of verbal descriptors of severity of breathlessness.37 Patients are asked to pick the verbal descriptor that best describes their perceived exertion during exercise. It is usually used in conjunction with an exercise protocol with standardized power output or metabolic loads. When used in this manner, the slope of the Borg descriptors over time is very reproducible and reliable, permitting comparisons within individuals and across population groups.38,39

The Reading Numbers Aloud test was designed as an objective measure of the activity-limiting effect of breathlessness in people with cancer who were breathless at very low levels of exertion.40 The test involves asking subjects to read a grid of numbers as quickly and clearly as possible for 60 seconds. The number of numbers read and the number read per breath are recorded.

**Dyspnea and Psychological Factors**

The person’s perception of the intensity of his or her breathlessness is also affected by psychological factors. Anxious, obsessive, depressed and dependent persons appear to experience dyspnea that is disproportionately severe relative to the extent of their pulmonary disease.4 Gift and colleagues34 found that anxiety was higher during episodes of high or medium levels of dyspnea, compared with low levels of dyspnea. Kellner and associates41 found in multiple regression analyses that depression was predictive of breathlessness. Studies in cancer patients by Dudgeon and Lertzman42 and others43,44,45 have also shown that anxiety is significantly correlated with the intensity of dyspnea \((r = 0.3)\) but explains only 9% of the variance in the intensity of breathlessness. These studies were done in people with chronic dyspnea and when the person was at rest. Carriher-Kohlman and colleagues46 found higher correlations between dyspnea intensity and anxiety associated with dyspnea at the end of exercise \((r = 0.49)\). It is also probable that anxiety is a more prominent factor during episodes of acute shortness of breath.

**Management**

The optimal treatment of dyspnea is to treat reversible causes. If this is no longer possible, then both nonpharmacological and pharmacological methods are used (Table 13–2).

**Pharmacological Interventions**

**Opioids.** Since the late 19th century, opioids have been used to relieve breathlessness of patients with asthma, pneumothorax, and emphysema.47 Although most trials have demonstrated the benefit of opioids for the treatment of dyspnea,48–50 some have been negative51–56 or have produced undesirable side effects.49,57

In 2001, a systemic review examined the effectiveness of oral or injectable opioid drugs for the palliative treatment of breathlessness.51 The authors identified 18 randomized, double-blind, controlled trials comparing the use of any opioid drug
against placebo for the treatment of breathlessness in patients with any illness. In the studies involving nonnebulized routes of administration, there was statistically strong evidence for a small effect of oral and parenteral opioids for the treatment of breathlessness.

In recent years, there has been tremendous interest in the use of nebulized opioids for the treatment of dyspnea. Opioid receptors are present on sensory nerve endings in the airways; therefore, it is hypothesized that if the receptors were interrupted directly, lower doses, with less systemic side effects, would be required to control breathlessness. The recent systematic review identified nine randomized double-blind, controlled trials comparing the use of nebulized opioids or placebo for the control of breathlessness. The authors concluded that there was no evidence that nebulized opioids were more effective than nebulized saline in relieving breathlessness. It is hard to justify the continued use of nebulized opioids.

Physicians have been reluctant to prescribe opioids for dyspnea since the potential for respiratory failure was recognized in the 1950s. The recent systematic review of opioids for breathlessness identified 11 studies that contained information on blood gases or oxygen saturation after intervention with opioids. Only one study reported a significant increase in the arterial partial pressure of carbon dioxide (PaCO₂), but it did not rise above 40 mm Hg. In studies of cancer patients, morphine did not compromise respiratory function as measured by respiratory effort and oxygen saturation or respiratory rate and PaCO₂. It is now known that the development of clinically significant hypoventilation and respiratory depression from opioids depends on the rate of change of the dose, the history of previous exposure to opioids, and possibly the route of administration. Early use of opioids improves quality of life and allows the use of lower doses while tolerance to the respiratory depressant effects develops.

**Table 13-2**

Management of Dyspnea

| Sit upright supported by pillows or leaning on overbed table |
| Fan ± oxygen |
| Relaxation techniques and other appropriate non-pharmacological measures |
| Identify and treat underlying diagnosis (if appropriate) |
| Pharmacologic Management |
| Chronic |
| Opioids |
| Add phenothiazine (chlorpromazine, promethazine) |
| Acute |
| Opioids |
| Add anxiolytic |

**Sedatives and Tranquilizers.** Chlorpromazine decreases breathlessness without affecting ventilation or producing sedation in healthy subjects. Woodcock and colleagues found that promethazine reduced dyspnea and improved exercise tolerance of patients with severe COPD. O'Neill and associates did not find that promethazine improved breathlessness in healthy people, nor did Rice and coworkers find that it benefited patients with stable COPD. McIver and colleagues found that chlorpromazine was effective for relief of dyspnea in advanced cancer.

The results of clinical trials to determine the effectiveness of anxiolytics for the treatment of breathlessness have also been quite variable. Two studies showed that diazepam was effective in treating dyspnea, and one showed a reduction in dyspnea. Greene and colleagues reported an improvement in dyspnea with alprazolam; however, a randomized, placebo-controlled, double-blind study did not find any relief of dyspnea with alprazolam. Clorazepate was not found to be effective for breathlessness. Buspirone, a nonbenzodiazepine anxiolytic, had no effect on pulmonary function tests or arterial blood gases in patients with COPD but improved exercise tolerance and decreased dyspnea. This drug warrants further study.

**Combinations.** In a double-blind, placebo controlled, randomized trial, Light and colleagues studied the effectiveness of morphine alone, morphine and promethazine, and morphine and prochlorperazine for the treatment of breathlessness in patients with COPD. The combination of morphine and promethazine significantly improved exercise tolerance without worsening dyspnea, compared with placebo, morphine alone, or the combination of morphine and prochlorperazine. Ventafridda and colleagues also found the combination of morphine and chlorpromazine to be effective.

**Other Medications.** Indomethacin reduced exercise-induced breathlessness in a group of normal adults, but no benefit was obtained in patients with diffuse parenchymal lung disease or COPD. Although inhaled bupivacaine reduced exercise-induced breathlessness in normal volunteers, it failed to decrease breathlessness of patients with interstitial lung disease. Inhaled lidocaine did not improve dyspnea in six cancer patients. Dextromethorphan did not improve breathlessness of patients with COPD. None of these medications can be recommended for the treatment of dyspnea at this time.

**Nonpharmacological Interventions**

**Oxygen.** The usefulness of oxygen for the terminally ill patient has been questioned. Most authorities currently recommend oxygen for dyspneic hypoxic patients, even in the face of increasing hypercapnia to achieve and maintain a PaO₂ of 55 to 60 mm Hg and an oxygen saturation of 88% to 90%. Bruera and colleagues demonstrated the benefit of oxygen therapy in 20 hypoxic patients with terminal cancer. Rating of dyspnea by the patient, respiratory rate, oxygen saturation, and respiratory effort all improved with oxygen to
Traditionally, tube thoracostomy was performed with large-bore chest tubes connected to wall suction; this treatment necessitated hospitalization and limited mobility, with substantial discomfort and expense. Recent studies have shown the effectiveness of small-bore catheters and indwelling small pleural catheters in the outpatient setting.108–110

Instillation of any of several sclerosing agents into the pleural space after adequate drainage by tube thoracostomy creates a chemical pleuritis that obliterates the pleural space and prevents pleural fluid reaccumulation. Because pleurodesis is often painful, intrapleural lidocaine is administered before the instillation of the sclerosing agent to reduce local pain. Patients also should be premedicated and should have adequate analgesic available after the procedure.

Pericardial Effusion. As in all other situations, the approach to management of a pericardial effusion depends on the person’s stage of disease, the prognosis, the potential benefits and complications, and the wishes of the patient and family. If pericardial tamponade with hemodynamic compromise is present and treatment is appropriate, an emergency pericardiocentesis is indicated, with aggressive intravenous fluid support and possible administration of a sympathomimetic agent to temporize.111 Hemodynamic improvement usually occurs with removal of 50 to 100 mL of pericardial fluid. Continuous drainage can be achieved by placement of an indwelling pigtail catheter or creation of a pericardial window, or by percutaneous balloon pericardotomy.112,113 Pericardial drainage can be followed by instillation of a sclerosing agent to obliterate the pericardial space.113 Radiation or systemic chemotherapy could be considered if appropriate.114

Nursing Interventions

Many patients obtain relief of dyspnea by leaning forward while sitting and supporting their upper arms on a table. This technique is effective in patients with emphysema,115 probably because of an improved length-tension state of the diaphragm, which increases efficiency.116

Pursed-lip breathing slows the respiratory rate and increases intrathoracic airway pressures, thus decreasing small airway collapse during periods of increased dyspnea.117 Mueller and coworkers67 found that pursed-lip breathing led to an increase in tidal volume and a decrease in respiratory rate at rest and during exercise in 7 of 12 COPD patients experiencing an improvement in dyspnea. Pursed-lip breathing reduces dyspnea in about 50% of patients with COPD.118

People who are short of breath often obtain relief by sitting near an open window or in front of a fan. Cold directed against the cheek119 or through the nose120,121 can alter ventilation patterns and reduce the perception of breathlessness, perhaps by affecting receptors in the distribution of the trigeminal nerve that are responsive to both thermal and mechanical stimuli.119,120

a statistically significantly greater degree than with air. In hypoxic patients with COPD, oxygen supplementation improved survival, pulmonary hemodynamics, exercise capacity, and neuropsychological performance.100 Guidelines for oxygen therapy are shown in Table 13–3.

The role of oxygen in the treatment of nonhypoxic dyspnea is less clear. Woodcock and coworkers103 studied the effect of oxygen on breathlessness in nonhypoxic patients with COPD. Oxygen not only reduced breathlessness but also increased the distance that the patients were able to walk. However, in a study of nonhypoxic cancer patients with dyspnea, Bruera and colleagues104 found no significant differences in dyspnea, fatigue, and distance walked between those who received oxygen or air during exercise.

Pleural Effusions. Whether a malignant pleural effusion requires treatment is determined by the degree of symptomatic compromise, the stage of the disease, the patient’s life expectancy, and the patient’s estimated tolerance for more aggressive therapeutic approaches.105,106 At the time of initial diagnostic or therapeutic tap of the pleural effusion, the removal of 500 to 1500 mL of pleural fluid helps predict response to further therapies.106 If symptoms are not relieved and the lung does not reexpand, then further thoracenteses or insertion of a chest tube is unlikely to be of any benefit, and treatment should include medications to relieve symptoms. In 97\% of cases, fluid reaccumulates within 1 month after thoracentesis alone.107 Repeated thoracenteses increase the risk for pneumothorax, empyema, and pleural fluid loculation and therefore should be limited to people with a short life span.

**Note:** The table and text are extracted from a medical textbook, and the information provided is intended for educational purposes. The content is subject to medical accuracy and should not be used as a substitute for professional medical advice.
Randomized controlled trials support the use of acupuncture and acupressure to relieve dyspnea in patients with moderate to severe COPD. Acupuncture provided marked symptomatic benefit in breathlessness and in respiratory rate in patients with cancer-related breathlessness. Other randomized controlled trials support the use of muscle relaxation with breathing retraining to reduce breathlessness in COPD patients.

Corner and colleagues found that weekly sessions with a nurse research practitioner over 3 to 6 weeks, using counseling, breathing retraining, relaxation, and coping and adaptation strategies, significantly improved breathlessness and ability to perform activities of daily living compared with controls. Carrieri and Janson-Bjerklie found that patients used self-taught relaxation to help control their breathlessness. Others have found that formal muscle relaxation techniques decrease anxiety and breathlessness. Guided imagery and therapeutic touch resulted in significant improvements in quality of life and sense of well-being in patients with COPD and patients with terminal cancer, respectively, without any significant improvement in breathlessness.

Nursing actions that intubated patients thought helpful included friendly attitude, empathy, providing physical support, staying at the bedside, reminding or allowing patients to concentrate on changing their breathing pattern, and providing information about the possible cause of the breathlessness and possible interventions.

Patient and Family Teaching

Carrieri and Janson-Bjerklie identified strategies patients used to manage acute shortness of breath. These strategies could be taught to patients and their families. Patients benefited from keeping still with positioning techniques, such as leaning forward on the edge of a chair with arms and upper body supported, and using some type of breathing strategy, such as pursed-lip or diaphragmatic breathing. Some of the patients distanced themselves from aggravating factors, and others used self-adjustment of medications. Several subjects isolated themselves from others to gain control of their breathing and diminish the social impact. Others used structured relaxation techniques, conscious attempts to calm down, and prayer and meditation. The study of Carrieri and Janson-Bjerklie and another by Brown and colleagues demonstrated that most subjects reported some changes in activities of living, such as changes in dressing and grooming, avoidance of bending or stooping, advanced planning or reduction in activities, staying in a good frame of mind, avoidance of being alone, and acceptance of the situation.

Patients and families should be taught about the signs and symptoms of an impending exacerbation and how to manage the situation. They should learn problem-solving techniques to prevent panic, ways of conserving energy, how to prioritize activities, use of fans, and ways to maximize the effectiveness of their medications, such as using a spacer with inhaled drugs or taking an additional dose of an inhaled beta-agonist before exercise. Patients should avoid activities in which their arms are unsupported, because these activities often increase breathlessness.

Patients in distress should not be left alone. Social services, nursing, and family input need to be increased as the patient’s ability to care for himself or herself decreases.

Case Study
Mrs. P, a 45-Year-Old Woman with Dyspnea

You are called to the room of Mrs. P and find her sitting at the bedside, gasping for breath. You know the Mrs. P is a 45-year-old woman with advanced ovarian carcinoma. She has known lung metastases and describes a progressive onset of worsening breathlessness with less and less activity. She says that she had gone to the washroom to have a sponge bath and while combing her hair got quite breathless and struggled to make it back to her bed. While getting an overbed table and pillow for her to rest on, you calmly instruct her to take slow, deep breaths and to use the breathing technique that you had previously taught her. You note that she is cyanosed and institute oxygen and fan to help relieve her breathlessness. On further examination, you find that her trachea is deviated to the right, there is dullness to percussion of her left chest, and there are decreased breath sounds in the left lung field. With institution of the oxygen, fan, and focused breathing, you note that she is slightly less distressed, but you ask her husband to stay with her while you prepare a dose of prn morphine. On your return 5 minutes later, Mrs. P’s breathing has further improved but is still a little labored, so you administer the morphine. Her husband stays with her, and 15 minutes later, when you return, he has helped her back into bed, where she is resting comfortably.

Summary

Dyspnea is a very common symptom in people with advanced disease. The symptom is often unrecognized and therefore the patients receive little assistance in managing their breathlessness. Dyspnea can have profound effects on the person’s quality of life, because even the slightest exertion may precipitate breathlessness.

Death Rattle

Noisy, rattling breathing in patients who are dying is commonly known as death rattle. This noisy, moist breathing can be very distressing for the family, other patients, visitors, and
health care workers, because it may appear that the person is drowning in his or her own secretions. Management of death rattle can present health care providers a tremendous challenge as they attempt to ensure a peaceful death for the patient.

Definition

Death rattle is a term applied to describe the noise produced by the turbulent movements of secretions in the upper airways that occur with the inspiratory and expiratory phases of respiration in patients who are dying.

Prevalence and Impact

Death rattle occurs in 23% to 92% of patients in their last hours before death. Studies have shown that there is an increased incidence of respiratory congestion in patients with primary lung cancer or cerebral metastases, with the symptom more likely to persist in cases with pulmonary pathology. The incidence of death rattle increases closer to death; the median time from onset of death rattle to death is 8 to 23 hours. Most commonly this symptom occurs when the person’s general condition is very poor, and most patients have a decreased level of consciousness. If the person is alert, however, the respiratory secretions can cause him or her to feel very agitated and fearful of suffocating. Despite the identification of “noisy breathing” as a problem in hospice, the identification of “noisy breathing” as a problem in hospice, the incidence of death rattle during the last hours or days of life varies statistically significantly between groups of hydrated patients and groups of dehydrated patients.

Pathophysiology

The primary defense mechanism for the lower respiratory tract is the mucociliary transport system. This system is a protective device that prevents the entrance of viruses, bacteria, and other particulate matter into the body. The surface of the respiratory tract is lined with a liquid sol phase near the epithelium and a superficial gel phase in contact with the air. Ciliated epithelial cells, located at all levels of the respiratory tract except the alveoli and the nose and throat, are in constant movement to propel the mucus up the respiratory tract, to be either subconsciously swallowed or coughed out. The mucus is produced by submucosal glands, which are under neural and humoral control. The submucosal glands are under parasympathetic, sympathetic, and noncholinergic nonadrenergic nervous control. Resting glands secrete approximately 9 mL/min., but mechanical, chemical, or pharmacological stimulation via vagal pathways of the airway epithelium can augment gland secretion. Surface goblet cells also produce mucus secretions, which can be increased with irritant stimuli (e.g., cigarette smoke). The secretory flow rate and amount, as well as the viscoelastic properties of the mucus, can be altered.

The audible breathing of the so-called death rattle is produced when turbulent air passes over or through pooled secretions in the oropharynx or bronchi. The amount of turbulence depends on the ventilatory rate and airway resistance. Mechanisms of death rattle include excessive secretion of respiratory mucus, abnormal mucus secretions inhibiting normal clearance, dysfunction of the cilia, inability to swallow, decreased cough reflex due to weakness and fatigue, and the supine recumbent position. Factors that may contribute to respiratory congestion include infection or inflammation, pulmonary embolism producing infarction and fluid leakage from damaged cells, pulmonary edema or CHF, dysphagia, and odynophagia. Although it has been suggested that a state of relative dehydration decreases the incidence of problematic bronchial secretions, Ellershaw and colleagues found no statistically significant difference in the incidence of death rattle in a biochemically dehydrated group of patients, compared with a group of hydrated patients.

Bennett proposed two types of death rattle. Type 1 involves mainly salivary secretions, which accumulate in the last few hours of life when swallowing reflexes are inhibited. Type 2 is characterized by the accumulation of predominantly bronchial secretions over several days before death as the patient becomes too weak to cough effectively. This characterization has been empirically supported by Morita and colleagues and therefore may prove useful to determine appropriate treatment.

Assessment

Assessment of death rattle includes a focused history and physical examination to determine potentially treatable underlying causes. If the onset is sudden and is associated with acute shortness of breath and chest pain, it might suggest a pulmonary embolism or myocardial infarction. Physical findings consistent with CHF and fluid overload might support a trial of diuretic therapy; the presence of pneumonia indicates a trial of antibiotic therapy. The effectiveness of interventions should be included in the assessment. The patient’s and family’s understanding and emotional response to the situation should also be assessed so that appropriate interventions can be undertaken.

A recently developed and validated assessment tool, the Victoria Respiratory Congestion Scale (VRCS), is clinically useful to determine the effectiveness of interventions. This instrument rates the congestion on a scale from 0 to 3 scale, with 0 indicating no congestion heard at 12 inches from the chest; 1 indicating congestion audible only at 12 inches from the chest; 2 indicating congestion audible at foot of patient's bed; and 3 indicating congestion audible at door of patient's room. This scale has demonstrated interrater reliability ($\kappa = 0.53$, $P < 0.001$) and concurrent validity with a noise meter ($P < 0.001$). It was weakly correlated with a caregiver distress scale ($\kappa = 0.24$, $P < 0.001$).
Management

Pharmacological Interventions

Primary treatment should be focused on the underlying disorder, if appropriate to the prognosis and the wishes of the patient and family. If this is not possible, then anticholinergics are the primary mode of treatment. Hyoscine hydrobromide (scopolamine), atropine sulfate, hyoscine butylbromide (Buscopan), and glycopyrrolate (Robinul) are the anticholinergic agents that are used to treat death rattle. Anticholinergic drugs can prevent vagally induced increased bronchial secretions, but they reduce basal secretions by only 39%. A recent evidence-based guideline stated that there is insufficient evidence to support the use of one drug over another and that the decision should be based on the drug characteristics and the needs of the patient.

**Hyoscine hydrobromide (scopolamine)** is the primary medication used for the treatment of death rattle. It inhibits the muscarinic receptors and causes anticholinergic actions such as decreased peristalsis, gastrointestinal secretions, sedation, urinary retention, and dilatation of the bronchial smooth muscle. It is administered subcutaneously, intermittently or by continuous infusion, or transdermally. In one study, hyoscine hydrobromide 0.4 mg subcutaneously was immediately effective and only 6% of the patients required repeated doses. In an open label study of the treatment of death rattle, 56% of patients who received hyoscine hydrobromide had a significantly reduced noise level after 30 minutes, compared with 27% of patients who had received glycopyrrolate ($P = 0.002$). In other studies, between 22% and 65% of patients did not respond to hyoscine hydrobromide, and secretions recurred from 2 to 9 hours after the injection. In a retrospective study of 100 consecutive deaths in a 22-bed hospice, 27% of patients received an infusion of hyoscine hydrobromide, with 5 of 17 requiring injections despite receiving an infusion.

**Atropine sulfate** is another anticholinergic drug that is preferred by some centers for the treatment of respiratory congestion. In a study of 995 doses of atropine, congestion was decreased in 30% of patients, remained the same in 69%, and increased in 1%. Atropine is the drug of choice of this group, because it results in less CNS depression, delirium, and restlessness, with more bronchodilatory effect, than hyoscine hydrobromide. There is, however, the risk of increased tachycardia with atropine sulfate when doses $>1.0$ mg are given. Hyoscine hydrobromide is thought to have a more potent effect on bronchial secretions than atropine does, but no comparative trials have been conducted in the palliative population.

**Glycopyrrolate (Robinul)** is also an anticholinergic agent. It has the advantages of producing less sedation and agitation and a longer duration of action than hyoscine hydrobromide. In two studies in which its effectiveness was compared with that of hyoscine hydrobromide, glycopyrrolate was not as effective in controlling secretions. However, others have disputed this finding and suggest it is also more cost-effective. Glycopyrrolate is available in an oral form and can be useful for patients at an earlier stage of disease, when sedation is not desired.

**Hyoscine butylbromide (Buscopan)** is another anticholinergic drug, but it has not been evaluated for its effectiveness in this condition. It is available in injection, suppository, and tablet forms.

Nonpharmacological Interventions

There are times when the simple repositioning of the patient may help him or her to clear the secretions (Table 13–4). Suctioning usually is not recommended, because it can be very uncomfortable for the patient and causes significant agitation and distress. Pharmacological measures are usually effective and prevent the need for suctioning. If the patient has copious secretions that can easily be reached in the oropharynx, then suctioning may be appropriate. In a study conducted at St. Christopher’s Hospice, suctioning was required in only 3 of 82 patients to control the secretions.

Patient and Family Teaching

The patient and the family can be very distressed by this symptom. It is important to explain the process, to help them understand why there is a buildup of secretions and that there is something that can be done to help. The Victoria Hospice group suggests using the term "respiratory congestion" as opposed to "death rattle," "suffocation," or "drowning in sputum," because these terms instill strong emotional reactions. When explaining to families the changes that can occur before death, this is one of the symptoms that should be mentioned. If the person is being treated at home, the family should be instructed as to the measures available to relieve death rattle and to notify their hospice or palliative care team if it occurs, so that appropriate medications can be ordered.

**Pharmacological management**

**Chronic**

- Glycopyrrolate or hyoscine hydrobromide patch

  *If treatment fails: subcutaneous hyoscine hydrobromide or subcutaneous atropine sulfate*

**Acute**

- Subcutaneous hyoscine hydrobromide or subcutaneous atropine sulfate
Mrs. S, a 60-year-old Woman with Metastatic Breast Cancer

When you start your shift and are walking down the hallway, you hear a loud gurgling noise as you pass Mrs. S’s room. You enter and find her family surrounding the bed and looking extremely distressed. Mrs. S. has very advanced metastatic breast cancer to lung, bones, and brain. Her condition has deteriorated markedly over the past few days. She is very restless and is pulling at the intravenous line that is running at 125 mL/h. There are audible gurgling sounds as she breathes, with diffuse crackles throughout her chest, and + pitting edema of all of her limbs. Her daughter, in tears, says, “It sounds like she is choking to death! Please do something!” While you help to reposition Mrs. S, you explain why this is happening and suction some of the mucus that has accumulated in her mouth. You go to the desk and get an order from the doctor for some furosemide, to change the intravenous line to a saline lock, and for an “as needed” dose of hyoscine hydrobromide subcutaneously. You administer the furosemide, but there is minimal improvement; therefore, you give Mrs. S an injection of hyoscine hydrobromide, and within 20 minutes she has settled.

Summary

Although death rattle is a relatively common problem in people who are close to death, very few studies have evaluated the effectiveness of treatment. Anticholinergics are the drugs of choice at this time. Death rattle can be a very distressing for family members at the bedside, and they need to receive good teaching and reassurance.

C O U G H

Cough is a natural defense of the body to prevent entry of foreign material into the respiratory tract. In people with advanced disease, it can be very debilitating, leading to sleepless nights, fatigue, pain, and at times pathological fractures.

Definition

Cough is an explosive expiration that can be a conscious act or a reflex response to an irritation of the tracheobronchial tree. Cough lasting < 3 weeks is considered acute, and that lasting > 8 weeks is considered chronic. A dry cough occurs when no sputum is produced; a productive cough is one in which sputum is raised. Hemoptysis occurs when the sputum contains blood. Massive hemoptysis is expectoration of at least 100 to 600 mL of blood in 24 hours.

Prevalence and Impact

Chronic cough is a common problem; recurrent cough is reported by 3% to 40% of the population. In population surveys, men report cough more frequently than women do, but women appear to have an intrinsically heightened cough response. Cough is often present in people with advanced diseases such as bronchitis, CHF, uncontrolled asthma, human immunodeficiency virus infection, and various cancers. In a study of 289 patients with non–small cell lung cancer, cough was the most common symptom (> 60%) and the most severe symptom at presentation. Eighty percent of the group had cough before death. Over time, cough and breathlessness were much less well controlled than the other symptoms in this group of patients.

In a study of 25 advanced cancer patients designed to evaluate treatment of cough, 88% of patients rated their cough as moderate or severe and 68% coughed > 10 times per day. Cough was found to interfere with breathing, sleep, and speech and was associated with coughing spasms, pain, nausea, and vomiting.

In patients with lung cancer, hemoptysis is the presenting symptom 7% to 10% of the time, 20% have it at some time during their clinical course, and 3% die of massive hemoptysis. The mortality rate of massive hemoptysis in patients with lung cancer can be as high as 59% to 100%.

Pathophysiology

Cough is characterized by a violent expiration, with flow rates that are high enough to sheer mucus and foreign particles away from the larynx, trachea, and large bronchi. The cough reflex can be stimulated by irritant receptors in the larynx and pharynx or by pulmonary stretch receptor, irritant receptor, or C-fiber stimulation in the tracheobronchial tree. Different mechanisms are involved in isolation or together in patients with cough of various causes. The vagus nerve carries sensory information from the lung that initiates the cough reflex. Infection can physically or functionally strip away epithelium, exposing sensory nerves and increasing the sensitivity of these nerves to mechanical and chemical stimuli. It is also thought that inflammation produces prostaglandins, which further increase the sensitivity of these receptors, leading to bronchial hyperreactivity and cough. When cough is associated with increased sputum production, it probably results from stimulation of the irritant receptors by the excess secretion. Cough is associated with respiratory infection, bronchitis, rhinitis, postnasal drip, esophageal reflux, medications including angiotensin-converting enzyme inhibitors, asthma, COPD, pulmonary fibrosis, CHF, pneumothorax, bronchiectasis, and cystic fibrosis. In the person with cancer, cough may be caused by any of these conditions; however, direct tumor effects (e.g., obstruction), indirect cancer effects (e.g., pulmonary emboli), and cancer treatment effects (e.g., radiation therapy) could also be the cause.
Hemoptysis can result from bleeding in the respiratory tract anywhere from the nose to the lungs. It varies from blood streaking of sputum to coughing up of massive amounts of blood. There are multiple causes of hemoptysis, but some of the more common causes are a tracheobronchial source, secondary to inflammation or tumor invasion of the airways; a pulmonary parenchymal source, such as pneumonia or abscess; a primary vascular problem, such as pulmonary embolism; a miscellaneous cause, such as a systemic coagulopathy resulting from vitamin K deficiency, thrombocytopenia, or abnormal platelet function secondary to bone marrow invasion with tumor, sepsis, or disseminated intravascular coagulation; or an iatrogenic cause, such as use of anticoagulants, nonsteroidal antiinflammatory drugs, or acetylsalicylic acid.160

**Assessment**

In assessing someone with cough, it is important to do a thorough history and physical examination. Because cough may arise from anywhere in the distribution of the vagus nerve, the full assessment of a patient with a chronic cough requires a multidisciplinary approach with cooperation between respiratory medicine, gastroenterology, and ear, nose, and throat (ENT) departments.154 The assessment helps to determine the underlying cause and appropriate treatment of the cough. Depending on the diagnosis, the prognosis, and the patient’s and family’s wishes, it may be appropriate to perform diagnostic tests, including chest or sinus radiography, spirometry before and after bronchodilator and histamine challenge, and, in special circumstances in people with earlier-stage disease, upper gastrointestinal endoscopy and 24-hour esophageal pH monitoring. In patients with significant hemoptysis, bronchoscopy is usually needed to identify the source of bleeding.

In the history and physical examination, one should look for a link between cough and the associated factors listed in the previous section, whether the cough is productive, the nature of the sputum, the frequency and amount of blood, precipitating and relieving factors, and associated symptoms.

**Management**

It is important to base management decisions on the cause and the appropriateness of treating the underlying diagnosis, compared with simply suppressing the symptom. This decision is based on the diagnosis, prognosis, side effects, and possible benefits of the intervention, and the wishes of the patient and family. Management strategies also depend on whether the cough is productive (Table 13–5). Theoretically, cough suppressants, by causing mucus retention, could be harmful in conditions with excess mucus production.157

**Pharmacological Interventions**

Antitussive drugs can be divided into two categories: centrally acting agents (opioids and nonopioids) and peripherally acting agents (which directly or indirectly act on cough receptors).156

### Centrally Acting Antitussives

**Opioids** suppress cough, but the dose is higher than that contained in the proprietary cough mixtures.157 The exact mode of action is unclear, but it is thought that opioids inhibit the mu receptor peripherally in the lung; act centrally by suppressing the cough center in the medulla or the brainstem respiratory centers; or stimulate the mu receptor, thus decreasing mucus production or increasing mucus ciliary clearance.157 Codeine is the most widely used opioid for cough; some authors claim that it has no advantages over other opioids and provides no additional benefit to patients already receiving high doses of opioids for analgesia,161 whereas others state that the various opioids have different antitussive potencies.156

More than 200 synthetic nonopioid antitussive agents are available; most are less effective than codeine.162 Dextromethorphan, a dextro isomer of levorphanol, is an exception; it is almost equiantitussive to codeine. Dextromethorphan acts centrally through nonopioid receptors to increase the cough threshold.163 Benzonatate is a nonopioid antitussive with a sustained cough-depressing action163 that provided excellent symptomatic relief for three cancer patients with opioid-resistant cough.164 Opioid and nonopioid antitussives may act synergistically,161 but further studies are needed to confirm this hypothesis.

**Peripherally Acting Antitussives**

**Demulcents** are a group of compounds that form aqueous solutions and help to alleviate irritation of abraded surfaces. They are often found in over-the-counter cough syrups. Their mode of action for controlling cough is unclear, but it is thought that the sugar content encourages saliva production and swallowing, which leads to a decrease in the cough reflex; stimulates the sensory nerve endings in the epipharynx, and decreases the cough reflex by a “gating” process; or the demulcents may act as a protective barrier by coating the sensory receptors.157

**Benzonatate** is an antitussive that inhibits cough mainly by anesthetizing the vagal stretch receptors in the bronchi, alveoli, and pleura.156 Other drugs that act directly on cough receptors include levodropropizine, oxalamine, and prenoxdiazine.156

Inhaled anticholinergic bronchodilators, either alone or in combination with a β₂-adrenergic agonists, effectively decrease cough in people with asthma and in normal subjects.165 It is thought that they decrease input from the stretch receptors,
thereby decreasing the cough reflex, and change the mucociliary clearance.

The local anesthetic lidocaine is a potent suppressor of irritant-induced cough and has been used as a topical anesthetic for the airway during bronchoscopy. Inhaled local anesthetics, such as lidocaine and bupivacaine, delivered by nebulizer, suppress some cases of chronic cough for as long as 9 weeks.\textsuperscript{157,166–168} Higher doses can cause bronchoconstriction, so it is wise to observe the first treatment. Patients must also be warned not to eat or drink anything for 1 hour after the treatment or until their cough reflex returns.

**Productive Coughs**

Interventions for productive coughs include chest physiotherapy, oxygen, humidity, and suctioning. In cases of increased sputum production, expectorants, mucolytics, and agents to decrease mucus production can be employed.\textsuperscript{136} Opioids, antihistamines, and anticholinergics decrease mucus production and thereby decrease the stimulus for cough.

**Massive Hemoptysis**

In patients with massive hemoptysis, survival is so poor that patients may not want any kind of intervention to stop the bleeding; in such cases, maintenance of comfort alone becomes the priority. For those patients who want intervention to stop the bleeding, the initial priority is to maintain a patent airway, which usually requires endotracheal intubation. Management options include endobronchial tamponade of the segment, vasoactive drugs, iced saline lavage, neodymium/yttrium-aluminum-garnet (Nd/YAG) laser photocoagulation, electrocautery, bronchial artery embolization, and external beam or endobronchial irradiation.\textsuperscript{135}

**Nonpharmacological Interventions**

If cough is induced by a sensitive cough reflex, then the person should attempt to avoid the stimuli that produce this. They should stop or cut down smoking and avoid smoky rooms, cold air, exercise, and pungent chemicals. If medication is causing the cough, it should be decreased or stopped if possible. If the cause is esophageal reflux, then elevation of the head of the bed may be tried. Adequate hydration, humidification of the air, and chest physiotherapy may help patients expectorate viscid sputum.\textsuperscript{98} Radiation therapy to enlarged nodes, endoscopically placed esophageal stents for tracheoesophageal fistulas, or injection of Teflon into a paralyzed vocal cord may improve cough.\textsuperscript{98}

**Patient and Family Education**

Education should include practical matters such as proper use of medications, avoidance of irritants, use of humidification, and ways to improve the effectiveness of cough. One such way is called “huffing.” The person lies on his or her side, supports the abdomen with a pillow, blows out sharply three times, holds the breath, and then coughs. This technique seems to improve the effectiveness of a cough and helps to expel sputum.

If the patient is having hemoptysis and massive bleeding is a possibility, it is important to educate the family about this possibility, to prepare them psychologically and develop a treatment plan. Dark towels or blankets can help to minimize the visual impact of this traumatic event. Adequate medications should be immediately available to control any anxiety or distress that might occur. Family and staff require emotional support after such an event.

**Case Study**

**RM, a 67-Year-Old Man with Non–Small Cell Carcinoma of the Lung**

RM is a 67-year-old man who presented to his family doctor 2 months ago with a 20-pound weight loss, hemoptysis, and shortness of breath. He was found to have an endobronchial adenocarcinoma of the lung with liver and bone metastases. He was treated with a course of radiotherapy, and the hemoptysis stopped. You are visiting him at home and find that he now has a dry, nonproductive cough that keeps him awake at night and is sometimes so forceful that he vomits. He is receiving hydromorphone 4 mg orally every 4 hours for pain. He has had a trial of demulcents, dextromethorphan, and opioids for his cough, with little effect. He has no evidence of pneumonia on physical examination but does have some scattered wheezes. You suggest a trial of inhaled Ventolin and Atrovent every 6 hours. When you next see him, he reports that his cough is much better and he has been able to get some rest.

**Summary**

Chronic cough can be a disabling symptom for patients. If the underlying cause is unresponsive to treatment, then suppression of the cough is the major therapeutic goal.

**References**

Key Points

- The urinary system is frequently the cause of bothersome or deleterious symptoms that affect the patient receiving palliative care.
- A malignancy or systemic disease may affect voiding function and produce urinary incontinence, urinary retention, or upper urinary tract obstruction.
- Frequent lower urinary tract symptoms (LUTS) include intermittent or continuous urinary leakage, daytime voiding frequency, excessive nocturia, bothersome urgency, feelings of incomplete bladder emptying, and the abrupt cessation of urination.
- Upper urinary tract symptoms include flank or abdominal pain and constitutional symptoms related to acute renal insufficiency or failure.
- Significant hematuria leading to clot formation and catheter blockage is an uncommon but significant complication of pelvic radiation therapy. Bleeding may occur months to years following radiotherapy.
- Initial treatment of hematuria includes continuous bladder irrigation to evacuate clots from the bladder vesicle until the fragile bladder wall heals. If hematuria recurs, more aggressive treatment options include intravesical alum or prostaglandins. Intravesical formalin treatments are reserved for very severe cases of blood loss.
- Bladder spasms may be associated with urinary tract infection or catheter blockage, or they may be idiopathic. Any apparent underlying cause of bladder spasms, such as a urinary tract infection, should be treated initially.
- An antimuscarinic medication should be used for long-term relief of bladder spasms. Extended-release or transdermal agents are usually preferred because of their favorable side effect profiles and avoidance of the need for frequent dosing. However, classic anticholinergic drugs may be required if bladder spasms prove refractory to extended or transdermal formulations.
- A suprapubic catheter may be used as an alternative to urethral catheterization after urethral trauma or in the presence of urethral obstruction in cases of urethral injury, strictures, prostate obstruction, after gynecologic surgery, or for long-term catheterization.

In many ways, the techniques used for management of urinary symptoms are similar to those used for patients in any care setting. However, in contrast to traditional interventions, the evaluation and management of urinary tract symptoms in the palliative care setting are influenced by considerations of the goals of care and closeness to death.

Urinary system disorders may be directly attributable to a malignancy, systemic disease, or a specific treatment such as radiation or chemotherapy. This chapter provides a detailed overview of the anatomy and physiology of the urinary system, which serves as a framework for understanding of the pathophysiology of bothersome symptoms and their management. This is followed by a review of commonly encountered urinary symptoms seen in the palliative care setting, including bothersome lower urinary tract symptoms (LUTS), lower urinary tract pain, urinary stasis or retention, and hematuria.

Lower Urinary Tract Disorders

Lower Urinary Tract Physiology

The lower urinary tract comprises the bladder, urethra, and supportive structures within the pelvic floor (Figures 14–1 and 14–2). Together, these structures maintain urinary continence, which can be simply defined as control over bladder filling and storage and the act of micturition. Continence is modulated by three interrelated factors: (1) anatomic integrity of the urinary tract, (2) control of the detrusor muscle, and (3) competence of the urethral sphincter mechanism.1,2 Each may be compromised in the patient receiving palliative care, leading to bothersome LUTS, urinary retention, or a combination of these disorders.
Anatomic Integrity

From a physiological perspective, the urinary system comprises a long tube originating in the glomerulus and terminating at the urethral meatus. When contemplating urinary continence, anatomical integrity of the urinary system is often assumed, particularly because extraurethral urinary incontinence (UI) is uncommon. However, anatomical integrity may be lost in the patient receiving palliative care due to a fistula that bypasses the urethral sphincter. This epithelialized tract allows continuous urinary leakage, which varies from an ongoing dribble in a patient with otherwise normal urine elimination habits to total UI characterized by failure of bladder filling and micturition.

Control of the Detrusor

In addition to a structurally intact urinary system, continence requires volitional control over detrusor contraction. Control of this smooth muscle can be conceptualized on three levels. Multiple modulatory centers within the central nervous system modulate the detrusor reflex, allowing inhibition of detrusor activity until the person wishes to urinate. Detrusor control is also influenced by its histological characteristics. The nervous control of the detrusor relies on input from multiple modulatory areas within the brain and spinal cord. Bilateral detrusor motor areas are found within the lobes of the frontal cortex. This modulatory center interacts with neurons in the thalamus, hypothalamus, basal ganglia, and cerebellum to modulate bladder filling and voiding. The net effect of these areas on continence is the maintenance of a stable detrusor that does not contract, even when provoked, until the person desires to urinate.

Whereas modulatory centers within the brain are essential for continence, the primary integration centers for bladder filling and micturition are found within the brainstem. Specific areas within the brainstem control bladder filling and storage under the influence of higher brain regions. These areas include the periaqueductal gray matter, which is responsible for coordinating multiple groups of neurons in the brainstem; the L and M regions, which modulate bladder filling and initiate the detrusor contraction; and the pontine micturition center, which coordinates the reflexive response of the urethral sphincter mechanism. Recognition of the significance of the brainstem micturition center is particularly important when providing palliative care, because a neurological lesion above the brainstem causes urge UI with a coordinated sphincter response, whereas lesions below this center affect bladder sensations and the coordination between the detrusor and the urethral sphincter.

The brainstem micturition center communicates with the bladder via spinal roots in the thoracolumbar and sacral segments. Segments in the thoracolumbar spine (T10–L2) carry sympathetic nervous impulses that promote bladder filling and storage, whereas segments S2–S4 transmit parasympathetic impulses to the bladder wall, allowing micturition under modulation by the brain and brain-stem. These impulses are carried through several peripheral nerve plexi, including the pelvic and inferior hypogastric plexi.

Histological characteristics of the detrusor also contribute to its voluntary control. Unlike the visceral smooth muscle of the bowel, stomach, or ureter, the detrusor muscle bundles are innervated on an almost one-to-one basis. The smooth muscle bundles of the detrusor also lack gap junctions, observed in other visceral organs, which allow propagation of a contraction independent of nervous stimulation. These characteristics
promote urinary continence because they discourage spontaneous contractions of the detrusor in response to bladder filling, as is characteristic of other visceral organs.

On a molecular level, specific chemical substances, commonly called neurotransmitters, exert local control over the detrusor. Several neurotransmitters are released from the axons of neurons within the bladder wall and act at specific receptors to produce smooth muscle contraction or relaxation. Norepinephrine acts through β3-adrenergic receptors, promoting detrusor muscle relaxation, and acetylcholine acts through muscarinic receptors, leading to detrusor contraction and micturition. Although it has long been known that the cholinergic receptors within the detrusor are muscarinic, physiological studies have identified at least five muscarinic receptor subtypes (M1 through M5). Receptor subtypes M2 and M3 predominate within the bladder wall and are primarily responsible for the detrusor contraction that leads to micturition. Identification of these receptor subtypes is clinically relevant because it has facilitated the development of drugs that act on the bladder but produce fewer side effects than the older (nonselective) drugs traditionally used to manage urge UI or bladder spasms.

**Competence of the Urethral Sphincter Mechanism**

The urethral sphincter comprises a combination of compressive and tension elements to form a watertight seal against urinary leakage, even when challenged by physical exertion or sudden increases in abdominal pressure caused by coughing, laughing, or sneezing. The soft urethral mucosa interacts with mucosal secretions and the submucosal vascular cushion to ensure a watertight seal that rapidly conforms to changes. Whereas the elements of compression provide a watertight seal for the urethra, striated and smooth muscle within the urethral sphincter mechanism (including the prostatic urethra in men), the rhabdosphincter smooth muscle of the bladder neck and proximal urethra promote sphincter closure when exposed to the neurotransmitter norepinephrine. Innervation of the rhabdosphincter is more complex. Acetylcholine acts on nicotinic receptors in the rhabdosphincter to stimulate muscle contraction. In addition, norepinephrine and serotonin (5HT) act on neurons within Onuf’s nucleus (located at sacral spinal segments 2 through 4), modulating rhabdosphincter tone during bladder filling and storage. A novel substance, duloxetine, is a balanced serotonin and norepinephrine reuptake inhibitor that is undergoing clinical investigation to determine its safety and efficacy for the management of stress urinary incontinence.

**Pathophysiology of Urinary Incontinence**

*Urinary incontinence* is defined as the uncontrolled loss of urine of sufficient magnitude to create a problem. It is initially characterized as acute or chronic, according to its presentation and underlying pathophysiology. Causes of acute UI may be classified according to the DIAPERS mnemonic (Table 14–1). Several conditions, including acute delirium, restricted mobility, stool impaction, and specific medications, may occur in patients receiving palliative care and should be considered when assessing and managing UI.

Chronic UI is subdivided into types according to its presenting symptoms or underlying pathophysiology. Stress UI occurs when physical stress (exertion) causes urine loss in the absence of a detrusor contraction. Two conditions lead to stress UI—urethral hypermobility (descent during physical activity) and intrinsic sphincter deficiency (incompetence of the striated or smooth muscle within the urethral sphincter mechanism).

UI, urinary incontinence
Although urethral hypermobility is rarely the primary cause of significant stress UI in the patient receiving palliative care, intrinsic sphincter deficiency may compromise sphincter closure and lead to severe urinary leakage. Intrinsic sphincter deficiency occurs when the nerves or muscles necessary for sphincter closure are denervated or damaged. Table 14–2 lists conditions that are likely to cause intrinsic sphincter deficiency in patients receiving palliative care.

Urge UI occurs when overactive detrusor contractions produce urinary leakage. Urge UI has recently been defined as part of a larger symptom syndrome called the overactive bladder. Overactive bladder is characterized by bothersome urgency with or without the symptom of urge UI. The diagnosis of overactive bladder is based on a combination of symptoms: diurnal voiding frequency, nocturia, bothersome urgency with or without the symptom of urge UI, and urinary leakage associated with a sudden desire to urinate. Approximately 36% of patients with overactive bladder syndrome experience urge UI. (The diagnosis of overactive bladder is based on a combination of symptoms: diurnal voiding frequency, nocturia, bothersome urgency with or without the symptom of urge UI, and urinary leakage associated with a sudden desire to urinate. A diagnosis of overactive bladder cannot be accurately inferred from a report of the symptom of urge UI alone.

Reflex UI is suspected in the patient who experiences a paralyzing neurological lesion that affects spinal segments below the brainstem and above S2. The patient frequently reports periodic urination with little or no warning and little or no associated urgency. The urinary stream may be intermittent (stuttering), and the patient may perceive a sensation of incomplete bladder emptying or report additional urinary leakage soon after completion of micturition.

Functional UI is suspected when a general evaluation of the patient reveals significant limitations in mobility, dexterity, or cognition. Continuous urinary leakage that is not associated with physical exertion raises the suspicion of extraurethral UI associated with a fistula, but it is also associated with severe stress UI caused by intrinsic sphincter deficiency.

Extraurethral UI occurs when a fistula creates an opening between the bladder and the vagina or skin, allowing urine to bypass the urethral sphincter. Within the context of palliative care, fistulas are usually caused by invasive pelvic or gynecological malignancies, extensive pelvic surgery, or radiation treatment.3

### Assessment and Management of Bothersome LUTS: Urinary Incontinence

The results of a focused history, physical assessment, urinalysis, and bladder log are essential for the evaluation of UI in the patient receiving palliative care. Urine culture and sensitivity testing, blood tests, urodynamic evaluation, or imaging studies also may be completed in specific cases.

The history focuses on the duration of the problem and the probable cause of bothersome symptoms. Acute UI is typically characterized by a sudden occurrence of urinary leakage or an acute exacerbation of preexisting symptoms. These symptoms are typically similar to those of urge or stress UI. In contrast, chronic or established UI usually evolves over a period of time, typically months or possibly years.

The history can also be used to provide clues about the type of chronic UI. Stress UI is characterized by urine loss occurring with physical exertion or a sudden increase in abdominal pressure caused by coughing or sneezing. It occurs in the absence of a precipitous and strong urge to urinate. Approximately 36% of patients with overactive bladder syndrome experience urge UI. (The diagnosis of overactive bladder is based on a combination of symptoms: diurnal voiding frequency, nocturia, bothersome urgency with or without the symptom of urge UI, and urinary leakage associated with a sudden desire to urinate. A diagnosis of overactive bladder cannot be accurately inferred from a report of the symptom of urge UI alone.

Reflex UI is suspected in the patient who experiences a paralyzing neurological lesion that affects spinal segments below the brainstem and above S2. The patient frequently reports periodic urination with little or no warning and little or no associated urgency. The urinary stream may be intermittent (stuttering), and the patient may perceive a sensation of incomplete bladder emptying or report additional urinary leakage soon after completion of micturition.

Functional UI is suspected when a general evaluation of the patient reveals significant limitations in mobility, dexterity, or cognition. Continuous urinary leakage that is not associated with physical exertion raises the suspicion of extraurethral UI associated with a fistula, but it is also associated with severe stress UI caused by intrinsic sphincter deficiency.

A focused physical examination provides additional evidence concerning the UI type and its severity. A general examination is used to evaluate the presence of functional UI and to determine the influence of functional limitations on other types of UI. A pelvic examination is completed to assess perineal...
Skin integrity, to identify the presence of obvious fistulas or severe sphincter incompetence, and to evaluate local neurological function. Altered skin integrity, particularly if accompanied by a monilial rash or irritant dermatitis, indicates high-volume (severe) urinary leakage. In certain cases, the source of severe leakage can be easily identified as a large fistula or massive intrinsic sphincter deficiency associated with a gaping (patulous) urethra. A local neurological examination, focusing on local sensations, pelvic floor muscle tone, and the presence of the bulbocavernous reflex, provides clues to underlying neurological problems leading to voiding dysfunction.

A bladder log (a written record of the timing of urination, volume, timing of UI episodes, and fluid intake) is useful because it allows a semiquantitative analysis of the patterns of urinary elimination, UI, and associated symptoms. It can also be used to assess fluid intake or the patient’s response to prompted voiding.22 The patient is taught to record the time of voluntary urination, episodes of incontinence and associated factors (urgency, physical activity), and type and amount of fluids consumed. This record is used to determine voiding interval, frequency of UI episodes along with associated factors, and the total volume and types of fluids consumed. Recording fluid intake allows the nurse to calculate the cumulative volume of fluids consumed each day, as well as the proportion of fluids containing caffeine or alcohol, substances that exacerbate bothersome LUTS. A 3-day bladder log is strongly recommended, but valuable information can be obtained from a 1- or 2-day document if a 3-day record is not available.23

Urinalysis serves several useful purposes in the evaluation of the patient with UI. The presence of nitrites and leukocytes on dipstick analysis or bacteriuria and pyuria on microscopic analysis indicates a clinically relevant urinary tract infection. Blood in the urine may coexist with a urinary tract infection, or it may indicate significant hematuria demanding prompt management (see later discussion). In the patient receiving palliative care, glucosuria may indicate poorly controlled diabetes mellitus causing osmotic diuresis and subsequent UI. In contrast, a low specific gravity may indicate diabetes mellitus or excessive fluid intake from oral or parenteral sources.

Other diagnostic tests are completed when indicated. For example, a urine culture and sensitivity analysis is obtained if the urinalysis reveals bacteriuria and pyuria, and an endoscopy is indicated if significant hematuria is present without an obvious explanation. Urodynamic testing is indicated after acute UI is excluded and if simpler examinations have failed to establish an accurate diagnosis leading to an effective plan for management.

The management of UI is based on its type, the desires of the patient and family, and the presence of complicating factors. Acute UI is managed by addressing its underlying cause.24 A urinary tract infection should be treated with sensitivity-driven antibiotics. Similarly, medication regimens are altered as feasible if they produce or exacerbate UI. Atrophic urethritis may be managed with topical hormone replacement if feasible. Alternatively, topical vitamin E preparations may offer some benefit if hormone replacement therapy is contraindicated. Fecal impaction must be relieved and constipation aggressively managed, using a combination of fluids and fiber. After disimpaction, a scheduled elimination program is frequently indicated. This program usually combines a peristaltic stimulant, such as a warm cup of coffee or tea or a suppository, and a scheduled elimination program. In addition, stool softeners or laxatives may be used if simpler programs fail to alleviate constipation. Refer to Chapter 11 for a detailed discussion of bowel elimination problems.

A number of techniques are used to manage chronic or established UI. Every patient should be counseled about lifestyle alterations that may alleviate or occasionally relieve UI and associated LUTS.25,26 Patients are advised to avoid routinely restricting fluid intake to reduce UI, because this strategy only increases the risk of constipation and concentrates the urine, irritating the bladder wall. Instead, they should be counseled to obtain the recommended daily allowance for fluids (30 mL/kg or 0.5 oz/lb),27 to sip fluids throughout the day, and to avoid intake of large volumes of fluids over a brief period. Patients may also be taught to reduce or avoid bladder irritants that increase urine production or stimulate detrusor muscle tone, including caffeine and alcohol, depending on the goals of care and the short-term prognosis.

Containment devices may be used to provide protection while treatments designed to address underlying UI are undertaken, or they may be used for added protection if these interventions improve but fail to eradicate urine loss.28 Women and men should be counseled about the disadvantages of using home products and feminine hygiene pads when attempting to contain urine. Specifically, they should be counseled that home products, such as tissues or paper towels, are not designed to contain urine and feminine hygiene products are designed to contain menstrual flow. As an alternative, patients should be advised about products specifically designed for UI, including disposable and reusable products, inserted pads, and containment undergarments.

If the patient experiences primarily stress UI, the initial management is with behavioral methods. Pelvic floor muscle training is strongly recommended for mild to moderate stress UI.29 Ideally, visual biofeedback is used to assist the patient to identify, isolate, and contract the pelvic floor muscles. If visual biofeedback is not available, vaginal palpation may be used to assist the patient to identify and contract the pelvic muscles. This task may be supplemented by asking the patient to occasionally interrupt the urinary stream during micturition, but this maneuver should not be routinely employed because it interferes with the efficiency of bladder evacuation. After the patient demonstrates mastery of muscle identification, isolation, and contraction, he or she is taught the “knack” of pelvic muscle contractions in response to physical exertion.30 This maneuver increases urethral closure and resistance to UI and relieves or sometimes corrects stress UI.

Medications also may be used to treat stress UI in selected cases.31 Pseudoephedrine, an α-adrenergic agonist, is available in
over-the-counter preparations (e.g., Sudafed SA). Imipramine, a tricyclic antidepressant with both α-adrenergic effects that increase urethral resistance and anticholinergic actions, may be useful for patients who experience stress UI or mixed stress and urge UI symptoms. Although these agents often alleviate stress UI, their potential benefits must be weighed carefully against their side effects. In addition to enhancing urethral sphincter closure, α-adrenergic agonists may cause tachycardia, restlessness, insomnia, and hypertension. Imipramine may produce these side effects as well as dysrhythmias and anticholinergic effects, including dry mouth, blurred vision, flushing, and heat intolerance. It also may affect the central nervous system and may be associated with short-term memory impairment, hallucinations, and nightmares. These side effects may be particularly significant in aged patients and in those with preexisting cognitive defects related to a primary tumor or disease.

An indwelling catheter may be indicated if intrinsic sphincter deficiency and subsequent stress UI are severe. Although not usually indicated, a larger catheter size may be required, to prevent urinary leakage (bypassing) around the catheter. A detailed discussion of catheter management is provided later in this chapter.

Overactive bladder dysfunction, with or without urge UI, is also managed by behavioral or pharmacological modalities (or both) whenever possible. In addition to the lifestyle and dietary factors discussed earlier, biofeedback methods are used to teach the patient to identify and contract the pelvic muscles. These skills are applied to a technique called urge suppression, which is used to inhibit specific episodes of urgency before UI occurs. When a sudden urge to urinate occurs, the patient is taught to stop, tighten the pelvic muscles in rapid succession using several “quick flick” contractions until the urge has subsided, and proceed to the bathroom at a normal pace. The patient also may be taught relaxation or other distraction techniques to cope with specific urge episodes. Behavioral methods are particularly helpful for the patient who is at risk for falling and related injuries.

Anticholinergic or antispasmodic medications also may be used to manage urge UI. A variety of agents are available, but three relatively new drugs, extended-release tolterodine (Detrol LA), extended-release oxybutynin (Ditropan XL), and transdermal oxybutynin (Oxytrol) are preferred because they are associated with fewer side effects when compared to other anticholinergic medications (Table 14-3).3,36 Anticholinergic medications work by increasing the functional bladder capacity, inhibiting overactive detrusor contractions, and reducing voiding frequency. Their principal side effect is dry mouth, which can be severe and can interfere with appetite and mastication.31 Other side effects include blurred vision, constipation, flushing, heat intolerance, and cognitive effects such as nightmares or altered short-term memory.

Although antispasmodic medications are often viewed as an alternative to behavioral therapies, they are better viewed as complementary modalities.37 Specifically, all patients who wish to use anticholinergic medications for urge UI should be advised to void according to a timed schedule (usually every 2 to 3 hours, depending on the urinary frequency documented on a bladder log obtained during assessment) and taught urge-suppression skills. Similarly, patients whose urge UI is not managed adequately by behavioral methods should be counseled about anticholinergic medications before placement of an indwelling catheter is recommended.

Intermittent catheterization or an indwelling catheter may be used in selected cases if urge UI is severe and proves refractory to other treatments. It is also indicated if urge UI is complicated by clinically relevant urinary retention or if the patient is near death and immobile.

Because reflex UI is typically associated with diminished sensations of bladder filling, it is not usually responsive to behavioral treatments. A minority of patients with reflex UI retain the ability to urinate spontaneously, but most cases must be managed with an alternative program. For men, a condom catheter may be used to contain urine. A condom that is latex free is typically selected. In some patients, an α-adrenergic blocking agent such as terazosin, doxazosin, tamsulosin, or alfuzosin is administered, to minimize obstruction caused by detrusor–sphincter dyssynergia.39 Intermittent catheterization is encouraged whenever feasible. The patient and at least one significant other should be taught a clean intermittent catheterization technique. For the patient with reflex UI, an anticholinergic medication is usually required in addition to catheterization, to prevent UI. If intermittent catheterization is not feasible, an indwelling catheter is used to manage reflex UI. Although the indwelling catheter is associated with serious long-term complications and is avoided in patients with spinal cord injury and a significant life expectancy, it is a more attractive alternative for the patient receiving palliative care.

Functional UI is treated by minimizing barriers to toileting and the time required to prepare for urination. Strategies designed to remove barriers to toileting are highly individualized and are best formulated with the use of a multidisciplinary team, combining nursing with physical and occupational therapy as indicated. Strategies used to maximize mobility and access to the toilet include using assistive devices such as a walker or wheelchair, widening bathroom doors, adding support bars, and providing a bedside toilet or urinal. The time required for toileting may be reduced by selected alterations in the patient’s clothing, such as substituting tennis shoes with good traction for slippers or other footwear with slick soles and substituting Velcro- or elastic-banded clothing for articles with multiple buttons, zippers, or snaps.

If the patient has significant contributing cognitive disorders, functional UI is usually managed by a prompted voiding program. Baseline evaluation includes a specialized bladder log, which is completed over a 48- to 72-hour period. The caregiver is taught to assist the patient to void on a fixed schedule, usually every 2 to 3 hours. The caregiver is taught to help the patient move to the toilet and prepare for urination; the caregiver also uses this opportunity to determine whether the pad incontinence brief reveals evidence of UI since the previous scheduled toileting. Patients who are successful, dry, and able

to urinate with prompting on more than 50% of attempts completed during this trial period are considered good candidates for an ongoing prompted voiding regimen; those who are unsuccessful are considered poor candidates and are managed by alternative methods, including indwelling catheterization in highly selected cases.

Because extraurethral UI is caused by a fistulous tract and produces continuous urinary leakage, it must be managed initially by containment devices and preventive skin care. The type of containment device depends on the severity of the UI; an incontinent brief is frequently required. Preventive skin care consists of routine cleansing with water and an incontinence

cleanser or mild soap, followed by thorough drying using a soft towel and hair dryer on the low (cool) setting. Additionally, a skin barrier may be applied if altered skin integrity is particularly likely.

In some cases, the fistula may be closed by conservative (non-surgical) means. An indwelling catheter is inserted, and the fistula is allowed to heal spontaneously. This intervention is most likely to work for a traumatic (postoperative) fistula. If the fistula is a result of an invasive tumor or radiation therapy, it is not as likely to heal spontaneously. In such cases, cauterization and fibrin glue may be used to promote closure. Alternatively, a suspension containing tetracycline may be prepared and used as a sclerosing agent. The adjacent skin is prepared by applying a skin barrier (e.g., a petrolatum-based ointment) to protect it from the sclerosing agent. Approximately 5 to 10 mL of the tetracycline solution is injected into the fistula by a physician, and the lesion is monitored for signs of scarring and closure. If UI persists for 15 days or longer, the procedure may be repeated under the physician’s direction. For larger fistulas or those that fail to respond to conservative measures, surgical repair is undertaken if feasible.

Assessment and Management of Bothersome LUTS: Urinary Stasis or Retention

A precipitous drop or sudden cessation of urinary outflow is a serious urinary system complication that may indicate oliguria or anuria (failure of the kidneys to filter the blood and produce urine), urinary stasis (blockage of urine transport from the upper to lower urinary tracts), or urinary retention (failure of the bladder to evacuate itself of urine). The following sections review the pathophysiology and management of urinary stasis or acute postrenal failure caused by bilateral ureteral obstruction and urinary retention.

Obstruction of the Upper Urinary Tract

Upper urinary tract stasis in the patient receiving palliative care is usually caused by obstruction of one or both ureters. The obstruction is typically attributable to a primary or metastatic tumor, and most arise from the pelvic region. In men, prostatic cancer is the most common cause, whereas pelvic (cervical, uterine, and ovarian) malignancies produce most ureteral obstructions in women. In addition to malignancies, retroperitoneal fibrosis secondary to inflammation or radiation may obstruct one or both ureters. Unless promptly relieved, bilateral ureteral obstruction leads to acute renal failure with uremia and elevated serum potassium, which can cause life-threatening arrhythmias.

When a single ureter is obstructed, the bladder continues to fill with urine from the contralateral (unobstructed) kidney. In this case, urinary stasis produces symptoms of ureteral or renal colic. Left untreated, the affected kidney is prone to acute failure and infection, and it may produce systemic hypertension because of increased renin secretion.

Urinary Retention

Urinary retention is the inability to empty the urinary bladder despite micturition. Acute urinary retention is an abrupt and complete inability to void. Patients are almost always aware of acute urinary retention because of the increasing suprapubic discomfort produced by bladder filling and distention and the associated anxiety. Chronic urinary retention occurs when the patient is partly able to empty the bladder by voiding but a significant volume of urine remains behind. Although no absolute cutoff point for chronic urinary retention can be defined, most clinicians agree that a residual volume of 200 mL or more deserves further evaluation.

Urinary retention is caused by two disorders, bladder outlet obstruction or deficient detrusor contraction strength. Bladder outlet obstruction occurs when intrinsic or extrinsic factors compress the urethral outflow tract. For the patient receiving palliative care, malignant tumors of the prostate, urethra, or bladder may produce anatomic obstruction of the urethra, whereas lesions affecting spinal segments below the brainstem micuiturition center but above the sacral spine cause functional obstruction associated with detrusor–sphincter dyssynergia. In addition, brachytherapy may cause inflammation and congestion of the prostate, producing a combination of urinary retention and overactive bladder dysfunction. In the patient receiving palliative care, deficient detrusor contraction strength usually occurs as a result of denervation or medication. Alternatively, it may result from histological damage to the detrusor muscle itself, usually caused by radiation therapy or by detrusor decompensation after prolonged obstruction. Neurological lesions commonly associated with deficient detrusor contraction strength include primary or metastatic tumors affecting the sacral spine or spinal column, multiple sclerosis lesions, tertiary syphilis, and diseases associated with peripheral polyneuropathies, such as advanced-stage diabetes mellitus or alcoholism. Poor detrusor contraction strength also may occur as a result of unavoidable denervation from large abdominopelvic surgeries, such as abdominoperineal resection or pelvic exenteration.

Assessment and Management of Upper Tract Obstruction and Urinary Retention

Accurate identification of the cause of a precipitous drop in urine output is essential, because the management of upper urinary tract obstruction and of urinary retention are different. Because both conditions cause a precipitous drop in urinary output, the LUTS reported by the patient may be similar. Both may cause difficulty initiating urination and a dribbling, intermittent flow, or both may produce few or no bothersome symptoms in some instances. However, upper urinary tract obstruction is more likely to produce flank pain, whereas acute urinary retention is more likely to produce discomfort localized to the suprapubic area. The flank pain associated with upper urinary tract obstruction is usually localized to one or both flanks, although it may radiate to the abdomen and even to the labia or testes if the
lower ureter is obstructed. Its intensity varies from moderate to intense. It typically is not relieved by changes in position, and the patient is often restless. The discomfort associated with acute urinary retention is typically localized to the suprapubic area or the lower back. The patient with acute urinary retention also may feel restless, although this perception is usually attributable to the growing and unfulfilled desire to urinate.

A focused physical examination assists the nurse to differentiate urinary retention from upper urinary tract obstruction. The patient with bilateral ureteral obstruction and acute renal failure may have systemic evidence of uremia, including nausea, vomiting, and hypertension. In some cases, obstruction may be complicated by pyelonephritis, causing a fever and chills. An abdominal assessment also should be performed. Physical assessment of the patient with upper urinary tract obstruction reveals a nondistended bladder, whereas the bladder is grossly distended and may extend above the umbilicus in the patient with acute urinary retention. Blood analysis reveals an elevated serum creatinine, blood urea nitrogen, and potassium in the patient with bilateral ureteral obstruction, but these values are typically normal in the patient with urinary retention or unilateral ureteral obstruction. Ultrasonography of the kidneys and bladder reveals ureterohydronephrosis above the level of the obstruction or bladder distention in the patient with acute urinary retention.

In contrast to the patient with ureteral obstruction or acute urinary retention, many patients with chronic retention remain unaware of any problem, despite large residual volumes of 500 mL or more. When present, LUTS vary and may include feelings of incomplete bladder emptying, a poor force of stream, or an intermittent urinary stream. Patients are most likely to complain of diurnal voiding frequency and excessive nocturia (often arising four times or more each night), but these symptoms are not unique to incomplete bladder emptying. Although acute renal failure is uncommon in the patient with chronic urinary retention, the serum creatinine concentration may be elevated, indicating renal insufficiency attributable to lower urinary tract pathology.

Obstruction of the upper urinary tract is initially managed by reversal of fluid and electrolyte imbalances and prompt drainage. Urinary outflow can be reestablished by insertion of a ureteral stent (drainage tube extending from the renal pelvis to the bladder) via cystoscopy. A ureteral stent is preferred because it avoids the need for a percutaneous puncture and drainage bag. In the case of bilateral obstruction, a stent is placed in each ureter under endoscopic guidance; a single stent is placed if unilateral obstruction is diagnosed. The patient is advised that the stents will drain urine into the bladder. However, because the stents often produce bothersome LUTS, the patient is counseled to ensure adequate fluid intake while avoiding bladder irritants, including caffeine and alcohol. In certain cases, an anticholinergic medication may be administered to reduce the irritative LUTS or bladder spasms that sometimes are associated with a ureteral stent.

If the ureter is significantly scarred because of radiation therapy or distorted because of a bulky tumor, placement of a ureteral stent may not be feasible and a percutaneous nephrostomy tube may be substituted. The procedure may be done in an endoscopy suite or an interventional radiographic suite under local and systemic sedation or anesthesia. Unlike the ureteral stent that drains into the bladder, the nephrostomy tube is drained via a collection bag. The patient and family are taught to monitor urinary output from the bag and to secure the bag to the lower abdomen or leg in a manner that avoids kinking. The success of placement of a ureteral stent or nephrostomy tube is measured by the reduction in pain and in serum creatinine and potassium concentrations, indicating reversal of acute renal insufficiency.

Acute urinary retention is managed by prompt placement of an indwelling urethral catheter. The patient is closely monitored as the bladder is initially drained, because of the very small risk of brisk diuresis associated with transient hyperkalemia, hematuria, hypotension, and pallor. This risk may be further reduced by draining 500 mL, interrupted by a brief period during which the catheter is clamped (approximately 5 minutes), and followed by further drainage until the retained urine is evacuated; or by draining the bladder slowly using a small-bore tube or intravenous set. The catheter is left in place for up to 1 month; this allows the bladder to rest and recover from the overdistension typical of acute urinary retention. After this period, the bladder may be slowly filled with saline, preferably heated to body temperature, and the catheter removed. The patient is allowed to urinate, and the voided volume is measured. This volume is compared with the volume infused, to estimate the residual volume; or a bladder ultrasound study can be completed to assess the residual volume. If the patient is able to evacuate the bladder successfully, the catheter is left out and the patient is taught to recognize and promptly manage acute urinary retention. If the patient is unable to urinate effectively, the catheter may be replaced or an intermittent catheterization program may be initiated, depending on the cause of the retention and the patient’s ability to perform self-catheterization.

The patient with chronic urinary retention may be managed by behavioral techniques, intermittent catheterization, or an indwelling catheter. Behavioral methods are preferred because they are noninvasive and not associated with any risk of adverse side effects. Scheduled toileting with double voiding may be used in the patient with low urinary residual volumes (approximately 200 to 400 mL). The patient is taught to attempt voiding every 3 hours while awake and to double void (urinate, wait for 3 to 5 minutes, and urinate again before leaving the bathroom). Higher urinary residual volumes and clinically relevant complications caused by urinary retention, including urinary tract infection or renal insufficiency, are usually managed by intermittent catheterization or an indwelling catheter.

Many factors enter into the choice between intermittent and indwelling catheterization, including the desires of the patient and family, the presence of obstruction or low bladder wall compliance (e.g., a small or contracted bladder), and the prognosis. From a purely urological perspective, intermittent catheterization is preferable because it avoids long-term
complications associated with an indwelling catheter, including chronic bacteriuria, calculi, urethral erosion, and catheter bypassing. However, an indwelling catheter may be preferable in a palliative care setting when the urethra is technically difficult to catheterize, the patient has a small capacity with low bladder wall compliance, the patient is experiencing significant pain or limited upper extremity dexterity that interferes with the ability to effectively evacuate the bladder via micturition, or UI is complicated by retention.

Managing the Indwelling Catheter

Although the decision to insert a catheter may be directed by a physician or nurse practitioner, decisions concerning catheter size, material of construction, and drainage bag are usually made by the nurse. 20,52,53 A relatively small catheter is typically sufficient to drain urine from the bladder. A 14- to 16-Fr catheter is adequate for men and a 12- to 14-Fr catheter is usually adequate for women. Larger catheters (16 to 20 Fr) are reserved for patients with significant intrinsic sphincter deficiency, hematuria, or sediment in the urine. Silastic, Teflon-coated tubes are avoided if the catheter is expected to remain in place more than 2 to 3 days. Instead, a silicone- or hydrophilic, low-friction catheter is selected because of its reduced affinity for bacterial adherence and increased comfort.

In men, water-soluble lubricating jelly should be injected into the urethra before catheterization, and in women such jelly should be liberally applied to the urethral meatus and adjacent mucosa before catheterization. A lubricant containing 2% Xylocaine may be used to reduce the discomfort associated with catheter insertion. The catheter is inserted to the bifurcation of the drainage port. A 5-mL balloon is filled with 10 mL to fill the dead space in the port while ensuring proper inflation, and the inflated balloon is gently withdrawn to near the bladder neck.

A drainage bag that provides adequate storage volume and reasonable concealment under clothing should be chosen. A bedside bag is preferred for bed-bound patients and for overnight use in ambulatory persons. The bedside bag should hold at least 2000 mL, should contain an antireflux valve to prevent retrograde movement of urine from bag to bladder, and should include a drainage port that is easily manipulated by the patient or care provider. In contrast, a leg bag is preferred for ambulatory patients. It should hold at least 500 mL, should be easily concealed under clothing, and should attach to the leg by elastic straps or a cloth pocket rather than latex straps, which are likely to irritate the underlying skin.

The patient is taught to keep the drainage bag level with or below the symphysis pubis and to secure the catheter so that unintentional traction against the thigh is avoided. Typically, the patient is encouraged to drink at least the recommended daily allowance of fluids, and to drink additional fluids if hematuria or sediment is present. However, these recommendations may be altered depending on the clinical setting and the patient’s short-term prognosis. The catheter is routinely monitored for blockage caused by blood clots, sediment, or kinking of the drainage bag above the urinary bladder. The patient and family are also advised to monitor for signs and symptoms of clinically relevant infection, including fever, new hematuria, or urinary leakage around the catheter. They are also advised that bacteriuria is inevitable, even with the use of catheters containing a bacteriostatic coating, and that only clinically relevant (symptomatic) urinary tract infections should be treated.

CASE STUDY
DY, a Patient with an Indwelling Catheter, Hematuria, and Clot Retention

DY is a 69-year-old white woman with type 2 diabetes mellitus, hypertension, and idiopathic cirrhosis with a mild coagulopathy. She was diagnosed with endometrial cancer at age 69 years and treated with external beam radiation therapy and interstitial radium seed implants. She began noting LUTS, including frequency, urgency, and dysuria, and she developed gross hematuria with clots approximately 3 years after completing radiation therapy. She was initially treated with continuous bladder irrigation, intravesical alum, and prostaglandin instillations with minimal response. She underwent a cystoscopy for evacuation of blood clots. At that time, random bladder biopsies were obtained, which revealed chronic inflammation, hemorrhage, hemosiderin-laden macrophages, and vascular telangiectasia. There was no evidence of malignancy. Several areas of bleeding were cauterized. Hyperbaric oxygen therapy was attempted, but the patient did not tolerate the procedure well and refused further treatments. Over the next 3 months, she continued to have intermittent episodes of gross hematuria and progressive weakness.

DY again sought assistance when she experienced a particularly severe episode of hematuria with clot retention and a hematocrit of 12%. She was admitted to hospital for transfusions and management of recurring hemorrhagic cystitis. A voiding cystourethrogram (VCUG) was obtained on admission, and she was treated with transfusions and continuous bladder irrigations until her sixth hospital day, when she was taken to the operating room for a cystoscopy, performed under anesthesia. Before the cystoscopy, Vaseline gauze was placed on the perineal skin. Because left vesicoureteral reflux was noted on the VCUG, a Fogarty balloon was passed into the distal left ureter and inflated to occlude the ureter. The bladder was filled, and her capacity was determined to be 300 mL. A total of 150 mL of a 3% formalin solution was slowly infused into the bladder and retained for 20 minutes. The bladder was then drained and irrigated with saline. A three-way indwelling catheter was placed, and continuous bladder irrigation was restarted. Her hematuria partially resolved, and she returned to the operating room 3 days later for instillation of 150 mL of a 3% formalin solution. The hematuria resolved after this second instillation, and the continuous bladder irrigation was discontinued within 24 hours.
At the time of discharge the next day, she was voiding well and her urine remained free of hematuria. Postprocedure pain was managed by a combination of urinary analgesics, such as phenazopyridine (Pyridium), and an oral narcotic analgesic (oxycodone). Both medications were discontinued 1 week after the final instillation.

Four months later, DY presented with recurrent dysuria, hematuria, and clots requiring transfusion and repeated cystoscopy with instillation of a 1% formalin solution. She responded to this treatment and was discharged 2 days after treatment.

This case demonstrates the risk of recurrent hemorrhagic cystitis after treatment with a combination of external beam and interstitial radiotherapy. This patient’s coagulopathy may have exacerbated the risk for significant hematuria. In this case, the initial episode of hematuria occurred 3 years after therapy, and it recurred over a period of 22 months despite treatment with continuous bladder irrigation, cystoscopy with electrocauterization, hyperbaric oxygen, intravesical alum, and prostaglandin. Ultimately, the condition failed to respond to intravesical instillation of a 1% formalin solution, but it did respond to a 3% solution. Nonetheless, the patient experienced a single recurrence within a period of 4 months, which responded to a single instillation of a 1% formalin solution. She remained symptom-free at 1 year.

Fortunately, life-threatening blood loss is a rare complication of hemorrhagic cystitis and bladder tumors. Treatment usually begins with bladder irrigation, evacuation of clots, and intravesical instillations such as alum or silver nitrate and progresses to therapy with intravesical prostaglandin and formalin. Because of the significant risk of toxicity if formalin is absorbed, a Fogarty catheter must be introduced to prevent reflux of formalin into the upper urinary tract and renal capillaries. Alternatives include cystoscopy with electrical cautery or laser coagulation of individual bleeding sites. Selective embolization or ligation of the hypogastric artery, palliative cystectomy, or radical nephrectomy may be required as a last resort.

Assessment and Management of Bothersome LUTS: Bladder Spasm

Irritative LUTS, including a heightened sense of urgency and urethral discomfort, are common in patients with a long-term indwelling catheter or ureteral stent. In certain cases, these irritative symptoms are accompanied by painful bladder spasms. Bladder spasms are characterized by intermittent episodes of excruciating, painful cramping localized to the suprapubic region. They are caused by high-pressure, overactive detrusor contractions in response to a specific irritation.46 Urine may bypass (leak around) the catheter or cause urge UI in the patient with a stent. Painful bladder spasms may be the direct result of catheter occlusion by blood clots, sediment, or kinking; or they may be associated with a needlessly large catheter, an improperly inflated retention balloon, or hypersensitivity to the presence of the catheter or stent or to principal constituents. Other risk factors include pelvic radiation therapy, chemotherapeutic agents (particularly cyclophosphamide), intravesical tumors, urinary tract infections, and bladder or lower ureteral calculus.

Bladder spasms are managed by altering modifiable factors or by administering anticholinergic medications if indicated (Table 14-4). Changing the urethral catheter may relieve bladder spasms. An indwelling catheter is usually changed every 4 weeks or more often because of the risk of blockage and encrustation with precipitated salts, hardened urethral secretions, and bacteria.

In addition to changing the catheter, the nurse should consider altering the type of catheter. For example, a catheter with a smaller French size may be inserted if the catheter is larger than 16 Fr, unless the patient is experiencing a buildup of sediment causing catheter blockage. Similarly, a catheter with a smaller retention balloon (5 mL) may be substituted for a catheter with a larger balloon (30 mL), to reduce irritation of the trigone and bladder neck. Use of a catheter that is constructed of hydrophilic polymers or latex-free silicone may relieve bladder spasms and diminish irritative LUTS because of their greater biocompatibility when compared with Teflon-coated catheters.

Instruction about the position of the catheter, drainage tubes, and bags is reinforced; and the drainage tubes and urine are assessed for the presence of sediment or clots likely to obstruct urinary drainage. In certain cases, such as when the urethral catheter produces significant urethritis with purulent discharge from the urethra, a suprapubic indwelling catheter may be substituted for the urethral catheter. A suprapubic catheter also may be placed in patients who have a urethra that is technically difficult to catheterize, or who tend to encrust the catheter despite adequate fluid intake. Once established, these catheters are changed monthly, usually in the outpatient, home care, or hospice setting.

Patients with indwelling catheters who are prone to rapid encrustation and blockage present a particular challenge for the palliative care nurse. Options for management include frequent catheter changes (sometimes as often as one or two times per week) and irrigation of the catheter with a mildly acidic solution such as Renacidin. Irrigation may be completed once or several times weekly, and a small volume of solution is used (approximately 15 mL) to provide adequate irrigation of the catheter while avoiding irritation of the bladder epithelium.44

Bladder spasms also may indicate a clinically relevant urinary tract infection. The catheter change provides the best opportunity to obtain a urine specimen. This specimen should be obtained from the catheter and never from the drainage bag. Although bacteriuria is inevitable with a long-term indwelling catheter, cystitis associated with painful bladder spasms should be managed with sensitivity-guided antibiotic therapy.
The patient is taught to drink sufficient fluids to meet or exceed the recommended daily allowance of 30 mL/kg (0.5 oz/lb) whenever feasible. Reduced consumption of beverages or foods containing bladder irritants, such as caffeine or alcohol, also may alleviate bladder spasms in some cases.

If conservative measures or catheter modification fail to relieve bladder spasms, an anticholinergic medication may be administered. These medications work by inhibiting the overactive contractions that lead to painful bladder spasms. Table 14–4 summarizes the dosage, administration, and nursing considerations of common anticholinergic medications used to manage bladder spasms, as well as urge or reflex UI.

**CASE STUDY**

**BA, a 76-Year-Old Man with Advanced Prostate Cancer**

BA is a 76-year-old African-American man who presented with stage T4, Gleason grade 9, adenocarcinoma of the prostate gland at the time of initial evaluation. The initial management was by androgen deprivation therapy for 30 months, but BA then presented with a rising prostate-specific antigen (PSA) level and evidence of several metastatic lesions on follow-up imaging studies. His prostate cancer continued to progress despite maximal androgen ablation therapy, radiation therapy, and several courses of chemotherapy. Recently, he has experienced progressive difficulty urinating, recurring episodes of hematuria, and an episode of acute urinary retention that required placement of an indwelling catheter for 2 weeks. Attempts to discontinue the indwelling catheter were unsuccessful, and his postvoid residual urine volumes remained elevated at 500 to 670 mL. A number of bladder management options were discussed with the patient and his spouse, and both agreed that they wished to leave an indwelling catheter in place, to avoid the risk for recurring episodes of acute urinary retention and accompanying LUTS.

Initially, BA managed the catheter well, but he subsequently developed multiple painful bladder spasms, sometimes associated with catheter bypassing (leakage of urine around the catheter). A urine culture was obtained which revealed >10⁵ colony-forming units of *Proteus mirabilis*, pyuria, and microscopic hematuria. He was treated with a 10-day course of levofloxacin based on sensitivity reports. Within 3 days, the frequency and severity of his bladder spasms had diminished to two to three episodes per day, and leakage around the catheter had stopped entirely. A regimen
of Ditropan XL, 10 mg qd, was then started to alleviate residual bladder spasms. Telephone follow-up 2 weeks later revealed that his spasms had stopped altogether.

Hematuria

Hematuria is defined as the presence of blood in the urine. It results from a variety of renal, urological, and systemic processes. When gross hematuria was present as an initial complaint or finding in an adult, further evaluation in one study revealed that 23% of patients had an underlying malignancy. In the palliative care setting, hematuria occurs more commonly after pelvic irradiation or chemotherapy or as the result of a major coagulation disorder or a newly diagnosed or recurring malignancy.

Hematuria is divided into two subtypes according to its clinical manifestations. Microscopic hematuria is characterized by hemoglobin or myoglobin on dipstick analysis and more than 3 to 5 red blood cells (RBCs) per high-power field (hpf) under microscopic urinalysis, but the presence of blood remains invisible to the unaided eye. Macroscopic (gross) hematuria is also characterized by dipstick and microscopic evidence of RBCs in the urine, as well as a bright red or brownish discoloration that is apparent to the unaided eye.

In the context of palliative care, hematuria can also be subdivided into three categories depending on its severity: Mild hematuria is microscopic or gross blood in the urine that does not produce obstructing clots or cause a clinically relevant decline in hematocrit or hemoglobin. Moderate and severe hematuria are associated with more prolonged and high-volume blood losses; hematuria is classified as moderate if ≤6 units of blood is required to replace blood lost within the urine and as severe if ≥6 units is required. Both moderate and severe hematuria may produce obstructing clots that lead to acute urinary retention or obstruction of the upper urinary tract.

Pathophysiology

Hematuria originates as a disruption of the endothelial–epithelial barrier somewhere within the urinary tract. Inflammation of this barrier may lead to the production of cytokines, with subsequent damage to the basement membrane and passage of RBCs into the urinary tract. Laceration of this barrier may be caused by an invasive tumor, iatrogenic or other trauma, vascular accident, or arteriovenous malformation. Hematuria that originates within the upper urinary tract is often associated with tubulointerstitial disease or an invasive tumor, whereas hematuria originating from the lower urinary tract is typically associated with trauma, an invasive tumor, or radiation- or chemotherapy-induced cystitis.

In the patient receiving palliative care, significant hematuria most commonly occurs as the result of a hemorrhagic cystitis related to cancer, infection (viral, bacterial, fungal, or parasitic), chemical toxins (primarily from oxazaphosphorine alkylating agents), radiation, anticoagulation therapy, or an idiopathic response to anabolic steroids or another agent. Radiation and chemotherapeutic agents account for most cases of moderate to severe hematuria.

Radiation cystitis is typically associated with pelvic radiotherapy for cancer of the uterus, cervix, prostate, rectum, or lower urinary tract. Most of these patients (80% to 90%) experience bothersome LUTS (diurnal voiding frequency, urgency, and dysuria) that reach their maximum intensity near the end of treatment and subside within 6 to 12 weeks after cessation therapy. However, about 10% to 20% of patients experience clinically relevant cystitis that persists well beyond the end of treatment or occur months or even years after radiotherapy. In addition to bothersome LUTS, these patients experience pain and hematuria caused by mucosal edema, vascular telangiectasia, and submucosal hemorrhage. They also may experience interstitial and smooth muscle fibrosis with low bladder compliance and markedly reduced bladder capacity. Severe fibrosis associated with radiotherapy can lead to moderate to severe hematuria, as well as upper urinary tract distress (ureterohydronephrosis, vesicoureteral reflux, pyelonephritis, and renal insufficiency) caused by chronically elevated intravesical pressures.

Chemotherapy-induced cystitis usually occurs after treatment with an oxazaphosphorine alkylating agent, such as cyclophosphamide or ifosfamide. A urinary metabolite produced by these drugs, acrolein, is believed to be responsible. Hemorrhage usually occurs during or immediately after treatment, but delayed hemorrhage may occur in patients undergoing long-term therapy. The effects on the bladder mucosa are similar to those described for radiation cystitis.

Assessment

Because bleeding can occur at any level in the urinary tract from the glomerulus to the meatus, a careful, detailed history is needed to identify the source of the bleeding and to initiate an appropriate treatment plan. The patient should be asked whether the hematuria represents a new, persistent, or recurrent problem. This distinction is often helpful, because recurrent or persistent hematuria may represent a benign predisposing condition, whereas hematuria of new or recent onset is more likely to result from conditions related to the need for palliative care. A review of prior urinalyses also may provide clues to the onset and history of microscopic hematuria in particular. The patient is queried about the relation of grossly visible hematuria to the urinary stream. Bleeding limited to initiation of the stream is often associated with a urethral source, bleeding during the entire act of voiding usually indicates a source in the bladder or upper urinary tract, and bleeding near the termination of the stream often indicates a source within the prostate or male reproductive system.

The patient with gross hematuria should also be asked about the color of the urine: a bright red hue indicates fresh
blood, whereas a darker hue (often described as brownish, rust, or “Coke” colored) indicates older blood. Some patients with severe hematuria report the passage of blood clots. Clots that are particularly long and thin, resembling a shoestring or fishhook, suggest an upper urinary tract source; larger and bulkier clots suggest a lower urinary tract source.

The patient is asked about any pain related to the hematuria; this questioning should include the site and character of the pain and any radiation of pain to the flank, lower abdomen, or groin. Flank pain usually indicates upper urinary tract problems, abdominal pain radiating to the groin usually indicates lower ureteral obstruction and bleeding, and suprapubic pain suggests obstruction or infection causing hematuria.

In addition to questions about the hematuria, the nurse should ask about specific risk factors, including a history of urinary tract infections; systemic symptoms suggesting infection or renal insufficiency including fever, weight loss, rash, and recent systemic infection; any history of primary or metastatic tumors of the genitourinary system; and chemotherapy or radiation therapy of the pelvic or lower abdominal region. A focused review of medications includes all chemotherapeutic agents used currently or in the past and any current or recent administration of anticoagulant medications, including warfarin, heparin, aspirin, nonsteroidal antiinflammatory drugs, and other anticoagulant agents.

Physical Examination

Physical examination also provides valuable clues to the source of hematuria. When completing this assessment, the nurse should particularly note any abdominal masses or tenderness, skin rashes, bruising, purpura (suggesting vasculitis, bleeding, or coagulation disorders), or telangiectasia (suggesting von Hippel-Lindau disease). Blood pressure should be assessed, because a new onset or rapid exacerbation of hypertension may suggest a renal source for hematuria. The lower abdomen is examined for signs of bladder distention, and a rectal assessment is completed to evaluate apparent prostatic or rectal masses or induration.

Laboratory Testing

A dipstick and microscopic urinalysis is usually combined with microscopic examination when evaluating hematuria. This provides a semiquantitative assessment of the severity of hematuria (RBCs/hpf), and it excludes pseudohematuria (reddish urine caused by something other than RBCs, such as ingestion of certain drugs, vegetable dyes, or pigments).

Urinalysis provides further clues to the likely source of the bleeding. Dysmorphic RBCs, cellular casts, renal tubular cells, and proteinuria indicate upper urinary tract bleeding. In contrast, hematuria from the lower urinary tract is usually associated with normal RBC morphology.

Additional evaluation is guided by clues from the history, physical examination, and urinalysis. For example, the presence of pyuria and bacteriuria suggests cystitis as the cause of hematuria and indicates the need for culture and sensitivity testing. The calcium/creatinine ratio should be assessed in a random urine sample for patients with painful macroscopic hematuria, to evaluate the risk for stone formation, particularly for individuals with hyperparathyroidism or prolonged immobility. A random urine protein/creatinine ratio and measurement of the C3 component of complement are obtained in all patients with proteinuria or casts, to evaluate for glomerulopathy or interstitial renal disease. Further studies also may be completed, to evaluate the specific cause of hematuria and implement a treatment plan.

In selecting those who should undergo a more extensive evaluation, one should also consider the presence of other risk factors for urological cancer, such as age >40 years, tobacco use, analgesic abuse, pelvic irradiation, cyclophosphamide use, and occupational exposure to rubber compounds or dyestuffs.

Imaging Studies

Ultrasonography is almost always indicated in the evaluation of hematuria in the patient receiving palliative care. It is used to identify the size and location of cystic or solid masses that may act as the source of hematuria and to assess for obstruction, most stones, larger blood clots, and bladder-filling defects. An intravenous pyelogram also may be used to image the upper and lower urinary tracts, but its clinical use is limited by the risk of contrast allergy or nephropathy. Cystoscopy is performed if a bladder lesion is suspected, and ureteroscopy with retrograde pyelography may be completed if an upper urinary tract source of bleeding is suspected.

Management

The management of hematuria is guided by its severity and its source or cause. Preventive management for chemotherapy-induced hematuria begins with administration of sodium 2-mercaptoethanesulfonate (mesna) to patients receiving an alkylating agent for cancer. This is given parenterally, and it slows degradation of the metabolite postulated to cause chemotherapy-induced cystitis and hematuria, and it neutralizes acrolein (the metabolite postulated to cause chemotherapy-induced cystitis and hematuria) and slows degradation of the 4-hydroxy metabolites produced by administration of alkylating drugs. It is given with cyclophosphamide (20 mg/kg at time 0 and every 4 hours for 2 or 3 doses). When combined with vigorous hydration, it has been shown to protect the bladder from subsequent damage and hematuria.

Mild urinary retention is managed by identifying and treating its underlying cause. For example, sensitivity-guided antibiotics are used to treat a bacterial hemorrhagic cystitis, and extracorporeal lithotripsy may be used to treat hematuria associated with a urinary stone. While the hematuria persists, the patient is encouraged to drink more than the recommended daily allowance for fluids, to prevent clot formation and urinary retention. In addition, the patient is assisted in...
obtaining adequate nutritional intake to replace lost blood, and iron supplementation is provided if indicated.

In contrast to mild hematuria, moderate to severe cases often lead to the formation of blood clots, causing acute urinary retention and bladder pain. In these cases, complete evacuation of clots from the bladder is required before a definitive assessment and treatment strategy are implemented.46 A large-bore urethral catheter (24 or 26 Fr in the adult) is placed, and manual irrigation is performed with a Toomey syringe. The bladder is irrigated with saline until no further clots are obtained and the backflow is relatively clear.46 A 22- or 24-Fr three-way indwelling catheter is then placed, to allow continuous bladder irrigation using cold or iced saline. Percutaneous insertion of a suprapubic catheter is not recommended because of limitations of size and the potential to “seed” the tract if a bladder malignancy is present.

Unsuccessful attempts to place a urethral catheter or recurrent obstruction of the irrigation catheter provides a strong indication for endoscopic evaluation. Rigid cystoscopy is preferred because it allows optimal evacuation of bladder clots and further evaluation of sites of bleeding; retrograde pyelography or ureteroscopy may also be completed if upper urinary tract clots are suspected. Based on the findings of endoscopic evaluation, sites of particularly severe bleeding are cauterized or resected.

After the initial evacuation of obstructing clots, bladder irrigations or instillations may be completed if multiple sites of bleeding are observed or if the risk of recurrence is high, as in the case of radiation- or chemotherapy-induced hematuria. Table 14–5 summarizes agents used to stop moderate to severe hematuria and their route, administration, and principal nursing considerations.

CASE STUDY
FH, a 21-Year-Old Man with Muscular Dystrophy

FH is a 21-year-old man with Duchenne’s muscular dystrophy who was admitted to the hospital with tachypnea, respiratory distress, and increasing problems with handling his secretions or swallowing well. On examination, his weight was 28 kg, respiratory rate 36, pulse 144. In general, he was a very thin, frail-appearing man who could respond only by nodding his head or moving a few fingers. He had severe contractions of his extremities. His lips were dry and cracked, but his mucous membranes moist. On pulmonary examination, he had coarse breath sounds bilaterally with decreased sounds in the right base. His pulse rate was increased, but no murmurs were heard. Bowel sounds were present, but severe abdominal distension was noted. Genitourinary examination noted diaper containment. Erythema of the sacrum was present, but no skin breakdown was noted.

FH was admitted to the intensive care unit with a diagnosis of right lower lobe pneumonia. His course deteriorated, and he appeared septic with decreased cardiac output, requiring intubation and respiratory support. Because of decreased urine output, repeated attempts were made to place a Foley catheter without success, and eventually bleeding was noted from the urethra. At that time, both urology and surgery specialists were consulted. Plain abdominal radiographs were remarkable for profoundly distended bowel loops containing an enormous amount of fecal material. An attempt was made to manually disimpact without success. At the time of the urology consultation, blood was noted at the meatus and a decision was made to perform a bedside cystoscopic examination for direct visualization and catheter placement. A very dense stricture and a large false passage were noted at the bulbous urethra. The stricture would not accommodate the scope, so under direct vision the green wire was advanced through the correct lumen into the bladder. Dilators were passed sequentially up to 12 Fr, which was the largest size that could be accommodated. The 12-Fr dilator was then left in place overnight, and the decision was made to take FH to the operating room for suprapubic catheter placement and surgical bowel disimpaction. In the operating room, because of his body habitus and the fact that the bladder was displaced by bowel, ultrasound guidance was used and a 14-gauge Bonanno suprapubic tube was placed percutaneously, stitched into place and attached to a drainage bag.

Eventually, FH improved and was extubated, now with bilevel positive airway pressure with oxygen, and he was discharged home with Home Health nursing care in addition to in-home hospice care. FH had made himself a “Do Not Intubate” code status, and everyone anticipated imminent death.

FH was scheduled to return to clinic for a suprapubic catheter change 1 month after discharge. However, the family failed to keep this appointment. Six weeks after the 14-gauge Bonanno catheter had been placed, FH returned to the emergency room with an obstructed catheter, with the nurses and family reporting inability to flush the catheter on a regular basis. He had been voiding per urethra intermittently. The catheter would not flush, and a guide wire could not pass through it. Eventually, with ultrasound guidance, a new Bonanno SP tube catheter was placed, and instructions were given for flushing daily with normal saline. This catheter obstructed 21 days later and could not be irrigated. A guide wire was placed, and a new Bonanno catheter was inserted over the top of the wire. FH returned 10 days later to the angiography suite, where an Amplatz wire was placed down the indwelling catheter; the catheter was removed, and serial dilatation of the tract and fascia was then performed. Over the Amplatz wire, a 12-Fr Uresil nephrostomy tube was advanced into the bladder, and the distal coil was engaged. This was then connected to a drainage bag, and the patient was discharged home with a plan to return in 4 weeks for an upgrading in size and changing of the catheter. However, after 1 week the catheter became obstructed and was not flushed or drained. He was then taken to the operating room, where an open procedure was done to place an 18 Fr Foley catheter through a 22 Fr sheath. The balloon was inflated to 10 cc, and then the Foley was stitched in place and attached to a drainage bag. His subsequent bladder management program comprised daily normal saline flushes and outpatient Foley catheter changes monthly.

This case was particularly difficult in that FH was critically ill and unstable, and everyone thought death was imminent. The initial placement of a small Bonanno catheter was done because of his severe abdominal distention and stool impaction. The Bonanno catheter is only 14 gauge diameter and is made of Teflon, both factors that increase the risk of obstruction and encrustation. Daily irrigations with normal saline were ordered on discharge, but because a variety of home health nurses, hospice workers, and family members were involved in his care, there was confusion and the flushes were only being done as needed.

For long-term catheterization, the Bonanno-type suprapubic catheter, which is a Teflon catheter of only 14-gauge size, should not be used. The large-bore silicon Foley catheter (18 Fr and greater) is much preferred. The balloon should be inflated to at least 10 cc. If there are problems with the catheter coming out, a catheter with a 30-cc balloon could be used. Once the tract is matured with a good-sized catheter, the monthly replacement procedure can be taught to the home health or hospice nurse and done in the home.

It is recommended that an extra Foley catheter be kept in the home, so that if, for some reason, the catheter falls out, the nurse can immediately prepare the site with Betadine, lubricate the catheter, and insert it into the tract and bladder; otherwise, the tract tends to contract fairly quickly. The urology team must always be notified if there are problems with uncontrolled urine leakage, skin erosion, obstruction, hematoma formation, or symptoms of urinary tract infection.
Summary

Patients receiving palliative care frequently experience urinary system disorders. A malignancy or systemic disease may affect voiding function and produce UI, urinary retention, or upper urinary tract obstruction. In addition, upper acute renal insufficiency or renal failure may occur if the upper urinary tract becomes obstructed. These disorders may be directly attributable to a malignancy or systemic disease, or they may be caused by a specific treatment such as radiation, chemotherapy, or a related medication. Nursing management of patients with urinary system disorders is affected by the nature of the urological condition, the patient’s general condition, and the nearness to death.

This page intentionally left blank
Lymphedema and edema are frequently neglected by health providers. Lymphedema is caused by irreversible lymphatic transport capacity failure. Edema indicates that the capillary filtration rate exceeds lymphatic transport capacity. Long-term lymphedema management, including external compression, is fundamental to successful management.

Lymphedema and edema are seen regularly in palliative and acute care settings. Both are often neglected despite their capacity to cause pain, immobility, infection, skin problems, and significant patient distress. Long-term, neglected edemas, such as lower extremity venous insufficiency, can develop into chronic lymphedema. Discerning the difference between edema and lymphedema allows appropriate treatment. Because nurses have access to large, diverse patient populations, they constitute an ideal resource for improving patient care. This text prepares nurses to understand, assess, and manage both edema and lymphedema. Information is applicable to various clinical settings, including acute, outpatient, and palliative care.

Definitions

Edema, a symptom, refers to excessive accumulation of fluid within interstitial tissues. One or several factors precipitate an imbalance in extracellular fluid volume. Lymphedema is edema that arises principally from failure of lymphatic function. Lymphedema, a chronic disorder, results in both extracellular and lymphatic stasis. Excess fluids, proteins, immunological cells, and debris in affected tissues can produce chronic inflammation and connective tissue proliferation, including hypertrophy of adipose tissue. Some degree of progression usually occurs and can produce subcutaneous and dermal thickening and hardening. Lymphedema and edema are contrasted in Table 15–1, which provides definitions, signs and symptoms, and basic pathophysiology.

Prevalence

The world prevalence of edema is unknown, and that of lymphedema is poorly documented. Campisi estimated that the worldwide incidence of lymphedema, based on 1984 data, was some 150 million.
Secondary (acquired) lymphedema results from obstruction or obliteration of lymphatic channels. Cancer, trauma, surgery, severe infections, and immobilizing or paralyzing diseases are major causes of secondary lymphedema in developed nations. In industrialized nations with sophisticated cancer treatment facilities, secondary lymphedema occurs most often in breast cancer survivors undergoing standard axillary node dissections or radiation therapy or both. Prevalence has been reported as 20% to 28%. Sentinel node biopsy has, at least initially, decreased the incidence to 2% to 3%. Other cancers associated with lymphedema risk include breast, gynecological, and prostate cancers; sarcoma; melanoma; and lymphoma. Infection and thrombosis are known to precipitate lymphedema in patients treated for breast and other cancers.

*Source: References 2, 3, 107–110.*
Filariasis, a tropical disease in underdeveloped nations, is the predominant worldwide cause of secondary lymphedema. Mosquitoes transmit filariasis nematodes, which embed in human lymphatics to cause progressive lymphatic damage. Mortimer estimated the worldwide incidence of filariasis at 750 million. Sequelae are enormous from untreated lymphatic tissue destruction caused by this disease.

Currently, primary lymphedema is attributed to embryonic developmental abnormalities, which may be sporadic or part of a syndrome caused by either chromosomal abnormalities (e.g., Turner’s syndrome) or inherited single-gene defects. Prevalence documentation is poor but has been reported as 1 in every 6000 individuals, with a male-to-female ratio of 1:3.

Impact

Without proper management, lymphedema generally becomes worse over time and triggers a number of complications. Early diagnosis and long-term management are essential for complication avoidance and optimal outcomes. Research has documented numerous detrimental effects of lymphedema associated with breast cancer treatment, including varying levels of pain, fatigue, activity and exercise restriction, arm function losses, obvious disfigurement along with a sense of being different, depression and anxiety, and decreased sexual health. A sense of victory over cancer and full recovery are diminished by a visibly enlarged limb, which can potentially represent cancer recurrence and not just lymphatic dysfunction.

Additional potential sequelae include overall functional limitations capable of causing loss of self-sufficiency and long-term disability, skin changes and pathologies, and weight gain. Surgery or injury to the affected area increases the risk of both infection and progression. Prolonged stasis can lead to severe skin and tissue symptoms, sometimes referred to as elephantiasis. Symptoms include hyperkeratosis (hard, reptile-like skin), warts, and papillomas (engorged and raised lymph vessels on the skin surface). Chronic lymphedema, over a number of years, has also been associated with the development of the rare, usually fatal cancer, lymphangiosarcoma.

Anatomy, Physiology, and Pathophysiology

Edema

Edema is a symptom that results from an imbalance between capillary filtration and lymph drainage. Edema requires treatment of the underlying disorder that is precipitating tissue.

Figure 15–1. Major components of lymphatic circulation. Large lymph vessels and key concentrations of lymph nodes are displayed. One-way directional flow causes all lymph to move to the subclavian junctures via either the thoracic duct or the right lymphatic duct. The largest vessel, the thoracic duct, originates in the cisterna chyli. (Principles adapted from References 1–3, 25. Original drawing by Dale Matson, Penrose Cancer Center.)
fluid excess. Precipitators can include cardiac, hepatic, renal, allergic, or hypoproteinemic disease; venous obstruction; and medication complications22 (see Table 15–1). Edema can develop into secondary lymphedema after sufficient lymphatic damage, such as in venous insufficiency or fractures of the lower extremities.3,23,24

Lymphedema

A healthy lymphatic system helps regulate the tissue cellular environment, including collecting and returning plasma and proteins.3 Daily, 20% to 50% of the total accumulating plasma proteins travel through 2 to 4 L of lymph fluid in a healthy lymphatic system.25 Lymphatics also remove cellular waste products, mutants, and debris; eliminate nonself antigens, and regulate local immune defense in the process of maintaining homeostasis.3 Unidirectional vessels traverse from superficial to deep lymphatics through 600 to 700 lymph nodes, carrying lymph fluid to the venous system at the right or left venous angle of the anterior chest on either side of the neck (Figure 15–1). Lymph nodes purify lymph fluid, eliminating defective cells, toxins, and bacteria, explaining the increased risk of infection for patients with compromised lymphatics.3 Lymphedema pathology signifies malfunction in any part of the process of collecting, transporting, and depositing lymph into the venous system. Lymphedema pathophysiology signifies disruption of these processes and is described in Table 15–1.

Assessment

Physical assessment is the most common means of evaluating lymphedema.4 Assessment allows optimal management and fosters the well-known medical goal, “Do no harm.” Practitioner diagnostic tools are also available that provide insight and criteria for lymphedema assessment.1 No validated nursing lymphedema assessment tool exists. “Best Practice”26 components of lymphedema nursing assessment are displayed in Table 15–2.

The first assessment priority is proper diagnosis. For example, assessment revealed that early symptoms of congestive heart failure were responsible for a suspected lymphedema in one elderly, frail patient referred for lymphedema assistance. When the results of the physical assessment and patient history were combined with dialogue, the patient reported that she had replaced her cardiac medication with several natural supplements in order to save money and avoid “toxic drugs.” Edema resolved within several days after she resumed her cardiac medications. Some patients, especially those who are elderly, chronically ill, or significantly distressed, are not able to accurately provide a medical history. Requesting physician (physician assistant or nurse practitioner) dictations can provide excellent assessment information.

A patient health history questionnaire facilitates assessment. Useful health categories include patient demographics; health history; etiology; signs and symptoms; complications; work and household responsibilities; support people; spiritual health27; and lymphedema goals. Completion of the questionnaire before the initial assessment is performed improves assessment accuracy and content and allows additional time for important nurse–patient dialogue.28 Dialogue helps nurses gain essential patient knowledge: (1) view of lymphedema, (2) readiness for instruction and treatment, (3) pertinent work and lifestyle matters, (4) spiritual concerns, (5) illness and adjustment issues, and (6) desired goals. Often the patient’s initial goal is cure, which is unattainable. In this situation, the patient needs time to adopt new goals. Nurse awareness of patient quality-of-life goals29 fosters collaboration and management success. Instruction, support, multidisciplinary referrals, goal-setting, assistance with

Lymphedema Management

289

self-care, complication avoidance, and long-term management are improved by this knowledge.30,31

For example, a 58-year-old woman presented with large lower extremity primary lymphedema. She expressed a positive, easy-going life view; had a boyfriend, children, and grandchildren; cared for an elderly mother; and worked full-time, 50 miles away from home. Her stated treatment goal was to “wear boots.” If the nurse’s goals were complete limb reduction and perfect compliance, both the nurse and the patient would be likely to experience frustration and failure. This failure could cause the nurse to conclude that the patient’s poor outcome was caused by poor compliance. Alternatively, the nurse could incorporate the patient’s life view, goals, and responsibilities into a workable treatment and self-care program.

A definitive lymphedema diagnosis is often determined solely from a history and physical examination, especially if conservative management is planned and symptoms are not severe. Questionable clinical symptoms or etiology may require imaging evaluation. Lymphoscintigraphy (isotope lymphography) is currently the optimal lymphedema diagnostic test.1 Lymphography (direct), formerly the only test available, is now rarely used in lymphedema patients32 because of its potential to cause lymphatic injury and its inability to clarify function.3

Assessment for infection, thrombosis, or cancer metastasis (Figure 15–2) is required at every patient contact.33,34 Although later signs of infection or thrombosis are well known, awareness and careful assessment allow early diagnosis and treatment. Lymphedema progression or treatment resistance may be the earliest sign of complication or may represent a lack of response to current treatment. Changes in pain or comfort, skin (color, temperature, condition), or mobility and range of motion are other possible early signs of these three major complications.

**Figure 15–2.** Assessment of complications in lymphedema management. ADLs, activities of daily living; BMI, body mass index; BP, blood pressure; DO, doctor of osteopathy; F/U, follow-up; MD, doctor of medicine; NP, nurse practitioner; PA, physician assistant; PCP, primary care physician; TPR, temperature, pulse, and respirations; US, ultrasonography.
complications. Most infections develop subcutaneously, beneath intact skin. Cultures are not recommended, because they rarely document a bacterial source and can further increase the risk of infection. Suspected thrombosis or new or recurring cancer requires appropriate diagnostic evaluation (e.g., Doppler ultrasonography, magnetic resonance imaging, positron emission tomography, computed tomographic scanning). Venous ultrasonography is reported to be safer than venography for evaluation of suspected thrombosis in a limb with, or at high risk for, lymphedema.

Figure 15–2 depicts ongoing complication assessment and decision-making. Basic treatment of complications is also included. Signs and symptoms of metastasis can include pain, neuropathies, new masses or lesions, skin/tissue color and texture changes, and treatment-resistant rashes. For thrombosis, signs can include distended veins, venous telangiectasis, and rapid edema progression beyond the affected limb. Thrombosis requires anticoagulation, pain control, rest, and avoidance of use of external compression. Currently, no research clarifies the appropriate timing for use of compression after thrombosis, and the traditional 6-month delay until use of compression should be assumed. Discussion of this issue with the presiding physician is appropriate. Compression refers to the deliberate application of pressure to produce a desired clinical effect. In contrast, some physicians recommend the use of limb support for several days or longer after painful thrombosis-related swelling, especially in the presence of metastatic cancer. Support signifies the retention and control of tissue without application of pressure. Until research enables a practice standard, the presiding physician must determine the use and timing of support and compression.

A diagnosis of early thrombosis was achieved for a 67-year-old patient with advanced metastatic lymphoma and leukemia when left leg thrombosis developed rapidly while the patient was hospitalized for a cancer complication. Thrombosis encompassed the entire leg. During anticoagulation, leg edema, pain, and signs of venous insufficiency continued to progress. Several weeks later, the patient was referred to the clinical nurse specialist for assistance. Excess edema volume in the affected leg (compared with the nonaffected leg) was 94% (4816 mL). A Tensoshape product (BSN Medical Ltd., Brierfield, England) was provided (with physician approval) for 1 week, and 9% limb reduction was achieved. Good product tolerance was reported. A demonstration ContourSleeve (lower extremity, full-leg product that uses high-low foam and a spandex compression sleeve; Peninsula Medical, Inc., Scotts Valley, CA) was then provided with instructions to use it as tolerated, reverting to the Tensoshape product whenever the ContourSleeve was removed. One week later, follow-up assessment revealed edema reduction of 43%, compared with the initial volume. Excess volume had decreased from 94% to 54% (2730 mL). The patient also agreed to referral to a lymphedema therapist to obtain daytime compression stockings and to undergo several sessions of lymphatic drainage massage. Five weeks after the initial assessment, the patient returned for follow-up wearing her new stockings, her “tight-legged” slacks, her wig, and a large smile. Pain level, skin color and condition, gait, and range of motion of the ankle, knee, and hip were significantly improved (Figure 15–3A). Edema reduction in the lymphedema limb was 81%; excess volume was 18% (926 mL).

By 4½ months following the initial assessment, edema reduction had continued. Treatment included daytime stockings and ContourSleeve usage several nights a week. Edema reduction at this time was 87%. Excess limb volume, compared to the contralateral leg, was 12% (634 mL). Figure 15–3B displays improvement from the initial assessment through the 4-month follow-up.

Lymphedema Precautions

No research has demonstrated that “prevention” of lymphedema is possible. Rigid prevention measures may promote fears and frustration. The term “precaution” appears more accurate. One essential precaution is achieving and maintaining ideal body weight, because excess body weight is associated with decreased lymphatic function.

Infection prevention is a vital lymphatic function; infection is a significant risk factor and is the most frequent lymphedema complication. Risk increases with breaches in skin integrity. Blood withdrawal provides minimal risk because the skin puncture is small and no irritant is injected. Occasional drawing of blood, when no other reasonable option exists, is necessary for some patients. Patients can request an experienced phlebotomist and emphasize their increased infection risk. Subcutaneous, intramuscular, or intravenous injections can cause an allergic or inflammatory response and/or infection that compromises a weakened lymphatic system. These risks must be compared with the benefit and risk of use of a central venous catheter or suboptimal venipuncture site such as the lower extremity. Diabetes potentially increases breast cancer patients’ lymphedema risk when the affected limb is used for continual blood sticks or insulin injections. Patients with bilateral limb risk, especially of the upper extremities, face lifelong decisions regarding adherence to precautions.

Breast cancer disease and treatment factors are associated with increased lymphedema risk, including advanced cancer stage at diagnosis and radiation therapy to the axilla or supraclavicular area after a mastectomy. Box and associates provided excellent evidence regarding the benefit of early nurse interventions in decreasing the occurrence and severity of secondary lymphedema in breast cancer survivors. Nurses can assist high-risk patients by presenting or reinforcing precaution information and encouraging use of a compression sleeve at the earliest sign of edema. Emphasis on self-protection rather than rigid rules fosters patient empowerment. For example, an empowered patient assumes responsibility for reminding staff to avoid use of the affected arm rather than expecting medical personnel to remember to do so.

Exercise restrictions have long been recommended for breast cancer survivors. However, a growing body of evidence suggests that exercise does not necessarily increase lymphedema
Miller, a physical therapist, emphasized the important role exercise plays in general health, weight control, and quality of life. She explored the use of exercise to foster lymphatic function for breast cancer survivors. In addition to surgical recovery exercises, Miller oversaw progressive patient flexibility, strengthening, and aerobic exercises. She also established a guideline for monitoring limb exercise tolerance: (1) decrease exercise activity if any adverse response occurs (e.g., pain, increased edema, neurological changes); (2) decrease exercise if skin and tissue texture becomes firm and/or limb size increases for more than a brief period after exercise; and (3) consider the use of a compression garment during exercise. Although additional research is needed, preliminary research suggests that breast cancer survivors should be encouraged to carry out all postoperative exercises, resume normal precancer activities and be as fit as possible, while regularly monitoring their high-risk or affected limb.

**Long-Term Management Versus Treatment**

Edema usually subsides with proper treatment, whereas lymphedema requires long-term management. Components of long-term lymphedema management are listed in Table 15–3 and described throughout the chapter. Long-term management is a process of fostering optimal physical, functional, psychosocial, and spiritual wellness. Spiritual care guidelines have been gradually evolving in nursing for several decades. Spiritual care supports patients’ efforts to make meaning out of illness and to redefine themselves in their new state of being. Specific spiritual interventions can include (1) support during the struggle with and exploration of life’s ambiguities, (2) acknowledgment of patients’ real and potential losses and victories; and (3) guidance in patients’ exploration of end-of-life issues and decisions.

Long-term management requires quantification of ongoing patient, nurse, and program outcomes. Limb size is commonly used in both research and practice to evaluate treatment effectiveness. Other important objective outcomes include pain level, skin condition, range of motion of nearby joints, affected area and overall patient function, body mass index (BMI),
incidence of infection, and other complications.\textsuperscript{14,14,54,59,60} Patient self-care compliance and overall satisfaction are subjective outcomes that contribute to management success. Outcome measurement has been mandated by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO).\textsuperscript{58} Collecting and reviewing outcomes with patients over time fosters ongoing instruction, complication avoidance, sustained lymphedema improvement, and patient empowerment.\textsuperscript{19,31,61}

\textbf{CASE STUDY}

\textit{Mary, A Breast Cancer Survivor with Lymphedema}

Mary was diagnosed with breast cancer at age 60 years. Five years earlier, a diagnosis of polyradiculopathy had required early retirement from a demanding career. Every aspect of Mary’s life had been disrupted by this life-threatening muscle disorder. She had coped and adapted through adherence to a set schedule of daily activities, personal problem-solving, assertion of her locus of control, and her husband’s loving support.

Lymphedema manifested during radiation therapy, 4 months after conservative breast surgery that included standard axillary node dissection. Lymphedema was accompanied by erythema and petechiae, which varied in intensity throughout each day. Antibiotic therapy did not provide benefit and was poorly tolerated. Edema volume in the surgical arm, compared with the nonaffected arm, was 29\% (734 mL). No previous treatment had been available to Mary, who lived and received her breast cancer treatment 60 miles away from the lymphedema facility.

Mary was attentive and participatory during assessment and instruction. When a daytime compression garment was recommended, she emphatically rejected this treatment, convinced that the product would increase the symptoms of her muscle disorder. No data existed to support or refute this belief. Acceptance and support of Mary’s viewpoint validated her coping activities and fostered future self-care decision-making.\textsuperscript{57} Patient readiness for and acceptance of treatment is crucial to successful chronic disease management and warrants nurses’ patience.\textsuperscript{58} Mary agreed to use demonstration nighttime compression products (a ContourSleeve and Medi glove) for 6 to 8 hours at a time. Instruction was provided, including removal of the product (until she could speak with the clinical nurse specialist) if pain, numbness, tingling, infection, bleeding, or worrisome signs or symptoms occurred. One month later, she obtained her ContourSleeve and assumed full responsibility for regular replacement.

Over time, Mary gradually increased her product-wearing time. Eight months after assessment, she had achieved 45\% limb reduction. Excess limb volume, compared with the nonaffected arm, had decreased from 29\% to 16\% (405 mL). She never experienced pain or other neurological symptoms. One year after assessment, Mary requested assistance in obtaining a compression sleeve and glove for daytime use. Over the next several months, daytime compression resulted in an 83\% limb volume reduction compared with the initial pretreatment volume. Edema volume in the affected arm was reduced to 5\% (124 mL). Patient self-reported satisfaction and compliance with management was consistently high, and no limb complications occurred. Asymptomatic mild erythema has continued. Follow-up is currently every 6 months.

\textbf{Edema Treatment}

Edema treatment focuses on detection and intervention related to the causative factor or factors. Effective treatment stabilizes the interstitial fluid volume.\textsuperscript{7} Tissue support and/or gentle compression can be useful in relieving edema that might progress to lymphedema.

\textbf{Lymphedema Treatment}

Lymphedema treatment, evolving over the past 20 years, has lacked scientific rigor.\textsuperscript{52,63} Sequelae to the evidence deficit included (1) ongoing unsubstantiated treatment fads,\textsuperscript{64,65} (2) lack of practice and outcome standards, (3) lack of physician support and referrals,\textsuperscript{66,67} (4) inadequate third party payer reimbursement,\textsuperscript{58} and (5) reimbursement-driven rather than research-driven planning. For example, decongestive lymphatic therapy (DLT) is commonly recommended as the “gold standard” lymphedema treatment, and credentialing has been established.\textsuperscript{58,69} However, recent research in patients with breast cancer–related lymphedema indicates that compression bandaging alone provides limb reduction equivalent to that attained through bandaging combined with lymph drainage massage (LDM).\textsuperscript{68,69} Clearly, gold standard lymphedema treatment must be re-evaluated. Additionally, since no outcome standards exist to quantify current treatment outcomes, any treatment strategy can be called “successful,” and treatment results cannot be compared individually or in meta-analysis.\textsuperscript{69} Controlled trials are needed to provide evidence that allows establishment of valid practice and outcome standards, which must address cost-effectiveness, third party payer limitations, patient satisfaction, quality of life, and long-term outcomes.\textsuperscript{70}

Nevertheless, over the last few years, research has reported several treatment principles. Delay of lymphedema treatment and larger edema volumes are associated with poorer lymphedema treatment outcomes.\textsuperscript{71–74} Barriers to lymphedema treatment are time, cost, and lifestyle disruption.\textsuperscript{75} Thus, in conclusion, the research deficit has dramatically hindered lymphedema treatment efficacy, and this can only be addressed through appropriate scientific investigation.

\textbf{Infection Treatment}

Infection is the most common lymphedema complication.\textsuperscript{3} Lymph stasis, decreased local immune response, tissue...
congestion, and accumulated proteins and other debris foster infection.\textsuperscript{76} Traditional signs and symptoms (fever, malaise, lethargy, and nausea) are often present.\textsuperscript{14} Decades of literature support prompt oral or intravenous antibiotic therapy.\textsuperscript{3,5,7,78} Because streptococci and staphylococci are frequent precipitators, antibiotics must cover normal skin flora, as well as gram-positive cocci,\textsuperscript{79} and have good skin penetration.\textsuperscript{80} Early detection and treatment can help prevent the need for intravenous therapy and hospitalization.\textsuperscript{15} Intravenous antibiotic therapy is recommended for systemic signs of infection or insufficient response to oral antibiotics.\textsuperscript{80} Nursing activities include assisting patients in obtaining prompt antibiotic therapy, monitoring and reporting signs and symptoms, and providing instruction regarding high fluid intake, rest, elevation of the infected limb, and avoidance of strenuous activity. Garment-type compression is encouraged as soon as tolerable for lymphedema patients, and documentation of benefit has not been established.\textsuperscript{80,88,89} Patient avoidance of limb dependency, as possible, appears to be a more appropriate lymphedema precaution. Optimal patient self-care typically includes adherence to precautions, use of compression products and other treatments, weight management, fitness and lymphedema exercises, optimal nutrition and hydration, healthy lifestyle practices, and seeking assistance for lymphedema-related problems. Patient empowerment for optimal self-care is a great impetus to long-term management success.\textsuperscript{90}

For example, one female patient attended school, worked part-time, and was a single parent of two sons. She had experienced many lymphedema treatment failures after her initial presentation of lymphedema at age 5 years. Treatments had been painful, distressing, and unsuccessful. Emotional scars had resulted from having legs so different from those of her friends. Five years of intermittent support and encouragement were required to achieve patient treatment readiness. Achieving a successful treatment program required another year and included surgical repair of ingrown toenails. Use of outcomes provided concrete data that fostered excellent compression compliance (daytime garment and nighttime lower leg ContourSleeves). Ultimately, external compression reduced pain and fatigue sufficiently to allow 3 extra hours of activity per day. Long-term treatment success included sustained reduction of lymphedema and pain, elimination of recurrent infections, excellent compression compliance and self-care, high treatment satisfaction, and minimal need for lymphedema assistance.

**Exercise**

Exercise guidelines described earlier (see Lymphedema Precautions) are applicable for lymphedema management, including fitness exercise. Physician approval for exercise may be required. Cardiac or pulmonary disease and limb progression may require exercise restriction.\textsuperscript{88}

**Skin Care**

Diabetic-like care fosters skin health and integrity as well as infection prevention.\textsuperscript{55} Diligent care is especially important for patients with lower extremity, genital, breast, head, neck, or late-stage lymphedema, additional skin alterations, or unrelated debilitating conditions. Lymphedema can cause skin dryness and irritation, which is increased with long-term use of compression products. Bland, nonscented products are recommended for daily cleansing and moisturizing.\textsuperscript{76} Low pH moisturizers (e.g., AmLactin), which discourage infection, are recommended for advanced lymphedema, because skin and tissue changes increase infection risk. Water-based moisturizers, which are absorbed more readily, are less likely to damage compression products but are not suitable for all patients. Cotton clothing allows ventilation and is absorbent.

Advanced lymphedema can cause several skin complications, including lymphorrhrea, lymphoceles, papillomas, and hyperkeratosis. Lymphorrhrea is leakage of lymph fluid through the skin that occurs when skin cannot accommodate accumulated fluid. Nonadherent dressings, good skin care, and compression are used to alleviate leakage. Compression and good skin care also reduce the occurrence of lymphoceles, papillomas, and hyperkeratosis; these complications reflect skin adaptation to excess subcutaneous lymph.
External Compression

Because human skin expands as needed to maintain integrity, it does not resist progressive edema. External compression provides resistant pressure and is currently the most essential part of all lymphedema treatment.91 Physiological effects of compression include edema control or reduction, decreased accumulated protein, decreased arteriole outflow into the interstitium, improved muscle pump effect with movement and exercise of the affected area, and protection of skin. Gradient external pressure provides the greatest pressure distally and less pressure proximally; this is optimal for improved lymphatic transport.92 Compression that is not uniform on a limb (e.g., blood pressure cuffs, tourniquets, watches, elastic sleeves) can be detrimental by decreasing peripheral lymphatic function.

Bandages

Multilayer, low-stretch bandages provide external compression. They may be used as a single treatment modality, as part of DLT, or as part of a compression regimen that uses daytime garments and nighttime bandages. This third strategy is especially important for patients with severe lymphedema, such as can occur with morbid obesity or neglected primary lymphedema. Foam or other padding is often used under bandages to improve edema reduction and foster limb uniformity. The time, effort, and dexterity required for bandaging can become burdensome or impossible for some patients, necessitating the use of an alternative compression method. Kelly1 emphasized avoidance of bandaging because of arterial insufficiency in patients with an ankle/brachial index (ABI) of < 0.8.

Compression Garments

Compression garments are universally recommended for all patients with lymphedema of the extremities.98,101 Some experts have recommended early compression to manage lymphedema without the need for DLT.24,65,90 A national consensus meeting provided the following garment recommendations: (1) guidelines for selection and use of garments remain unclear; (2) cost and patient tolerance of the garments warrant consideration when prescribing; (3) hand swelling may develop or become problematic if an arm sleeve is used without hand protection, and patients should be made aware of this risk before obtaining a garment; (4) garments should be replaced after they lose elasticity; and (5) use of garments is recommended during physical activity and exercise.98 Garment use recommendations vary from daytime only, after DLT,101 to continual use as a first-line treatment.91 Svensson95 reported a 50% to 100% limb reduction through continual use of garments as a sole treatment. Bertelli and colleagues96 reported a 17% reduction with 6 hours of daily use of compression alone.

Garment usage requires frequent laundering of products (daily to every other day), daily skin care and complication monitoring, and 2 replacements every 6 months. Various helpful products exist to assist patients in applying garments, an especially important task for elderly and disabled patients. Hand arthritis or neuropathy can hinder tolerance of garments. Garment removal is required if compression causes pain, neurological symptoms, or color or temperature changes. Readjustment and movement may remedy the problem; often product replacement is required. Because a variety of products exist, staff and patient persistence is likely to result in good patient tolerance. Rubber gloves (dish-washing gloves) facilitate application of garments and extend their longevity. Timely garment replacement (usually every 6 months) is essential for good edema control.92

Other Compression Products

A growing number of alternative commercial compression products have become available. Semirigid products (e.g., Reidsleeve [Peninsula Medical, Inc., Scotts Valley CA], CircAid [CircAid, San Diego, CA]) use foam and Velcro straps to provide nonelastic compression designed to simulate bandaging while saving time and energy. JoVi (Innovative Medical Solutions, Inc., Selah, WA) and ContourSleeve products use foam and an outer spandex compression sleeve. The ContourSleeve allows adjustment for limb size changes, which can be ideal for limb reduction or increase or for weight changes affecting limb size. Distinct advantages of these products include ease and speed of application, overall comfort and tolerance, and product longevity. Haslett and Aitken97 reported that the Tribute Solaris (LymphatCare, New York, NY) appeared to contribute to maintenance of previously achieved DLT reduction. Lund88 reported that use of CircAid provided an acceptable substitute for bandaging. Research is needed to provide insight and direction regarding the use of these promising products.95 Use of CircAid products on the lower extremities is currently contraindicated with ABI < 0.8.98

Decongestive Lymphatic Therapy and Lymph Drainage Massage

DLT evolved in Europe when Michael Foldi86 combined Vodder’s Manual Lymph Drainage (MLD) technique with bandaging, exercises, and specialized skin care. Dr. Foldi described his four-modality lymphedema treatment as “Complete Decongestive Therapy” (CDT). Information has already been provided on skin care, exercise and compression. Vodder’s MLD technique consisted of a specialized light touch (skintouching) massage that stimulates peripheral lymphatics and assists lymph transport across watersheds to allow alternative transport routes. The term “Lymphatic Drainage Massage” (LDM) is used in this text. The National Lymphedema Network has established DLT credentialing in the United States. Nevertheless, two randomized controlled clinical trials have demonstrated that compression bandaging (CB) alone is as effective at reducing arm volumes in breast cancer–related lymphedema as CB in combination with LDM/MLD. Thus,
scientific research demonstrates that compression bandaging is the single most optimal lymphedema treatment.

**Pneumatic (Mechanical) Pumps**

Mechanical pumps use electricity to inflate a single-chamber or multichamber sleeve and produce external limb compression. A decreased tissue capillary filtration rate (documented by lymphoscintigraphy) produces tissue fluid reduction and, consequently, limb volume decrease. Lymph formation decreases, but lymph transport, which would address lymphedema pathophysiology, is not affected. Badger and coworkers initiated a Cochrane review of physical therapies used to treat lymphedema. Regarding pumps, she reported: (1) pumps are used as a way of both reducing lymphedema and controlling it; (2) opinion is divided on the use of pumps for lymphedema treatment; (3) pump use has reduced swelling, but concern exists regarding the way in which swelling is decreased as well as the rapid displacement of fluid elsewhere in the body; and (4) use of pumps does not eliminate the need for compression garments and may not provide more benefit than garments alone. Brennan and Miller presented a consensus view of reservations related to tissue injury from improper pump prescription and use. Investigations have reported several pump complications, including lymphatic congestion and injury proximal to the pump sleeve, increased swelling adjacent to the pump cuff in up to 18% of patients, lack of benefit in all but stage I (reversible) lymphedema, and development of genital lymphedema in up to 43% of patients with cancer-related lower extremity lymphedema. After more than 50 years of pump use in lymphedema care and long-established Medicare reimbursement, no guidelines exist, significant complications are reported, and research has not clarified benefit.

**Surgical Treatments**

For a number of decades, surgical intervention has been described as a last resort in the treatment of lymphedema. Several surgical interventions have been reported, including microsurgical anastomoses, debulking, and liposuction. Surgery does not cure lymphedema, and follow-up use of compression is necessary. Surgery has provided cosmetic improvement in eyelid or genital edema.

Liposuction surgery has demonstrated greater than 100% reduction for patients with treatment-resistant lymphedema. Lack of response to conventional treatment resulted from formation of excess subcutaneous adipose tissue secondary to slow or absent lymph flow. Liposuction has increased skin capillary blood flow and does not further impair already decreased lymph transport capacity in breast cancer patients with lymphedema. No surgical complications occurred in 81 patients over a period of 9 years (data collection is ongoing). The average percentage of limb reduction for all patients 1 or more years after surgery (including 78 breast cancer survivors) was 107%. Fifteen study patients who underwent liposuction 8 or more years previously had a mean limb reduction of 120%. Patients have maintained these excellent limb reductions with 24-hour use of Elvarex compression garments (BSN-JOBST, Inc., Emmerick, Germany) and regular follow-up.

**CASE STUDY**

**GR, a Breast Cancer Survivor with Resistant Lymphedema**

GR, a California breast cancer survivor, developed lymphedema in 1977; she intermittently used garments and pumps for the next two decades. After relocating to Colorado in 1996, she was assisted by a Lymphedema Clinical Nurse Specialist. Over the next 3 years, GR was referred for two courses of intensive DLT. The second course was provided at a well-known Arizona treatment center. Lymphedema gradually and continually progressed, in spite of good compliance to the use of compression products. The patient met liposuction surgery criteria and obtained third party payer approval for liposuction surgery in Sweden. Preoperatively, excess limb volume was 2315 mL; no pitting was present. The patient had agreed to lifelong use of compression and underwent liposuction surgery in April of 2001. The surgical aspirate contained 90% adipose tissue. One month after surgery, she had achieved 125% edema reduction.

Patient follow-up takes place at least every 6 months, and garments are replaced at each of these follow-ups. Three years after surgery, edema reduction was 119%. Hand edema has returned. GR has continued 100% compliance with use of compression products. She has also regained significant quality of life. In late 2004, GR began using a ContourSleeve at nighttime along with her Elvarex glove. She continues daytime use of the Elvarex sleeve and glove. Greater than 100% edema reduction has been maintained. GR reported relief at the variation between her daytime and nighttime products. Figures 15–4 and 15–5 display the results of lymphedema treatment for this patient.

**Pharmacological Interventions**

Pharmacological treatment of lymphedema is supportive and includes antimicrobials, antifungals, and diuretics. Infection treatment has already been described. Physicians commonly use diuretics to treat edema and lymphedema. Diuretics generally provide little benefit in normal lymphedema management, because they limit capillary filtration by reducing the circulating systemic blood volume. Depleted systemic fluid volume can lead to hypotension and altered electrolyte status while achieving minimal to no lymphedema volume reduction. Isotope lymphography has substantiated that removal of fluid from the blood of lymphedema patients decreases the rate of lymphatic drainage.
Diuretics can be useful in some lymphedema-related conditions, including lymphedema of mixed origin; effusion of lymph into body cavities or organs (abdomen, thorax, genitals); lymphatic obstruction associated with malignancy, especially in hard-to-treat areas; and short-term use after infection, thrombosis, or trauma.2,95

Unusual Lymphedemas

Palliative care may require the management of unusual and challenging lymphedema sites, such as breast, head, neck, trunk, or genitals.105 LDM, skin-softening techniques, foam chip pads, and external compression (if possible) are recommended.2 External compression may be achieved with collars, vests, custom pants or tights, scrotal supports,76 or spandex type exercise apparel. The assistance of occupational or physical therapists and a seamstress may be helpful. Nationally, instructional courses are available to provide guidance for managing these difficult lymphedemas.

Conclusion

Edema is a symptom usually relieved by addressing the causative factor. Lymphedema, often labeled as edema, is a chronic disorder that requires long-term management. Although external compression is essential to effective lymphedema management, third party payer reimbursement is inadequate and frustrating, patients are frequently fitted with products they cannot tolerate, and many patients have not been adequately prepared for compression products and therefore discontinue use when their product does not cure the lymphedema. Newer compression products, such as the CircAid,
Legacy, and ContourSleeve, offer exciting product alternatives but lack controlled research substantiation. Benefits of two commonly supported treatments, DLT and pneumatic compression pumps, have not been substantiated by randomized controlled clinical trials, according to several expert literature reviews. Controlled clinical trials are essential for establishing “gold standard” treatments and should be the basis for third party payer reimbursement. Research deficit has also precluded establishment of outcome and practice standards, allowing an “anything goes” treatment environment. Nevertheless, over the last 10 years, progress has been achieved in both lymphedema awareness and scientific research. Oncology nurses and other nurses have increasingly contributed to lymphedema management as they have improved cancer survivorship. Nursing’s unique focus and scope of practice is ideally suited to chronic illness management, both at entry and at the advanced practice levels. Combined with nurses’ immense and diverse patient contact, enormous potential exists for nurses to dramatically improve both edema and lymphedema management.

Skin Disorders: Pressure Ulcers—Assessment and Management

I always thought that bedsores came from neglect. I feel so guilty that I let this happen.

—A patient’s family member

Key Points

- Pressure ulcer prevention includes repositioning at frequent intervals, with attention to adequate pain relief interventions before movement.
- Palliative care for pressure ulcers includes attention to prevention measures, obtaining and maintaining a clean wound, management of exudates and odor, and prevention of complications such as wound infection.
- It is essential to involve caregivers and family members in the plan of care.

Palliative care for skin disorders is a broad area, encompassing prevention and care for pressure ulcers, management of malignant cutaneous wounds and fistulas, and management of stomas. The goals of treatment are often to reduce discomfort, manage odor and drainage, and provide for optimal functional capacity. In each area, involvement of the caregiver and family in the plan of care is important. Management of skin disorders involves significant physical care as well as attention to psychological and social care. To meet the needs of the patient and family, access to the multidisciplinary care team is crucial, and consultation by an Enterostomal Therapy nurse or a certified Wound, Ostomy, Continence nurse is highly desirable.

Because skin disorders are such an important issue in palliative nursing care, Chapter 16 has been divided into two distinct parts. Part 16A addresses pressure ulcers in depth, and Part 16B addresses tumor necrosis, fistulas, and stomas.

Definition

Pressure ulcers are areas of local tissue trauma that usually develop where soft tissues are compressed between bony prominences and external surfaces for prolonged periods. Mechanical injury to the skin and tissues causes hypoxia and ischemia, leading to tissue necrosis. Caring for the patient with a pressure ulcer can be frustrating for clinicians because of the chronic nature of the wound and because additional time and resources are often invested in the management of these wounds. Pressure ulcer care is costly, and treatment costs increase as the severity of the wound increases. Additionally, not all pressure ulcers heal, and many heal slowly, causing a continual drain on caregivers and on financial resources. The chronic nature of a pressure ulcer challenges the health care provider to design more effective treatment plans.

Once a pressure ulcer develops, the usual goals are to manage the wound and to support healing. However, some patients
will benefit most from a palliative care approach. Palliative wound care means that the goals are comfort and limiting the extent or impact of the wound, but without the intent of healing. Palliative care for chronic wounds, such as pressure ulcers, is appropriate for a wide variety of patient populations. Palliative care is often indicated for terminally ill patients, such as those with terminal-stage cancer or other diseases. Institutionalized older adults with multiple comorbidities and older adults with severe functional decline may also benefit from palliative care. Sometimes individuals with long-standing wounds and other life expectations benefit from a palliative care approach for a specified duration of time. For example, a wheelchair-bound young adult with a sacral pressure ulcer may make an informed choice to continue to be up in a wheelchair to attend school even though this choice severely diminishes the expectation for wound healing. The health care professional may decide jointly with the patient to treat the wound palliatively during this time frame.

The foundation for designing a care plan for the patient with a pressure ulcer is a comprehensive assessment. This is true even if the goals of care are palliative. Comprehensive assessment includes assessment of wound severity, wound status, and the total patient. Generally, management of the wound is best accomplished within the context of the whole person, particularly if palliation is the outcome. Assessment is the first step in maintaining and evaluating a therapeutic plan of care. Without adequate baseline wound and patient assessment and valid interpretation of the assessment data, the plan of care for the wound may be inappropriate or ineffective—at the least, it may be disjointed and fragmented due to poor communication. An inadequate plan of care may lead to impaired or delayed healing, miscommunication regarding the goals of care (healing versus palliation), and complications such as infection.

Pathophysiology of Pressure Ulcer Development

Pressure ulcers are the result of mechanical injury to the skin and underlying tissues. The primary forces involved are pressure and shear.\(^1\)\(^–\)\(^5\) Pressure is the perpendicular force or load exerted on a specific area; it causes ischemia and hypoxia of the tissues. High-pressure areas in the supine position are the occiput, sacrum, and heels. In the sitting position, the ischial tuberosities exert the highest pressure, and the trochanters are affected in the side-lying position.\(^2\)\(^,\)\(^6\)

As the amount of soft tissue available for compression decreases, the pressure gradient increases. Likewise, as the tissue available for compression increases, the pressure gradient decreases. For this reason, most pressure ulcers occur over bony prominences, where there is less tissue for compression.\(^7\) This relationship is important to understand for palliative care, because most of the likely candidates for palliative care will have experienced significant changes in nutritional status and body weight, with diminished soft tissue available for compression and a more prominent bony structure. This more prominent bony structure is more susceptible to skin breakdown from external forces, because the soft tissue that is normally used to deflect physical forces (e.g., pressure, shear) is absent. Therefore, the tissues are less tolerant of external forces, and the pressure gradient within the vascular network is altered.\(^8\)

Alterations in the vascular network allow an increase in the interstitial fluid pressure, which exceeds the venous flow. This results in an additional increase in the pressure and impedes arteriolar circulation. The capillary vessels collapse, and thrombosis occurs. Increased capillary arteriolar pressure leads to fluid loss through the capillaries, tissue edema, and subsequent autolysis. Lymphatic flow is decreased, allowing further tissue edema and contributing to the tissue necrosis.\(^3\)\(^,\)\(^5\)\(^,\)\(^7\)\(^–\)\(^9\)

Pressure, over time, occludes blood and lymphatic circulation, causing deficient tissue nutrition and buildup of waste products due to ischemia. If pressure is relieved before a critical time period is reached, a normal compensatory mechanism, reactive hyperemia, restores tissue nutrition and compensates for compromised circulation. If pressure is not relieved before the critical time period, the blood vessels collapse and thrombosis occur, causing tissue deprivation of oxygen, nutrients, and waste removal. In the absence of oxygen, cells utilize anaerobic pathways for metabolism and produce toxic byproducts. The toxic byproducts lead to tissue acidosis, increased cell membrane permeability, edema, and, eventually, cell death.\(^3\)\(^,\)\(^7\)

Tissue damage may also be caused by reperfusion and reoxygenation of the ischemic tissues or by postischemic injury.\(^10\) Oxygen is reintroduced into tissues during reperfusion after ischemia. This triggers oxygen free radicals, known as superoxide anion, hydroxyl radicals, and hydrogen peroxide, which induce endothelial damage and decrease microvascular integrity. Ischemia and hypoxia of body tissues are produced when capillary blood flow is obstructed by localized pressure. The degree of pressure and the amount of time necessary for ulceration to occur have been a subject of study for many years. In 1930, Landis,\(^11\) using single-capillary microinjection techniques, determined normal hydrostatic pressure to be 32 mm Hg at the arteriolar end and 15 mm Hg at the venular end. His work has served as a criterion for measuring occlusion of capillary blood flow. Generally, a range from 25 to 32 mm Hg is considered normal and is used as the marker for adequate relief of pressure on the tissues. In severely compromised patients, even this level of pressure may be too high.

Pressure is greatest at the bony prominence and soft tissue interface and gradually lessens in a cone-shaped gradient to the periphery.\(^2\)\(^,\)\(^12\)\(^,\)\(^13\) Therefore, although tissue damage apparent on the skin surface may be minimal, the damage to deeper structures can be severe. In addition, subcutaneous fat and muscle are more sensitive than the skin to ischemia. Muscle and fat tissues are more metabolically active and, therefore, more vulnerable to hypoxia with increased susceptibility to pressure damage. The vulnerability of muscle and fat tissues to pressure forces explains pressure ulcers, in which large areas of muscle and fat tissue are damaged yet the skin opening is relatively small.\(^8\) In patients with severe malnutrition and weight loss, there is less tissue between the bony prominence and the
surface of the skin, so the potential for large ulcers with extensive undermining or pocketing is much higher.

There is a relationship between intensity and duration of pressure in pressure ulcer development. Low pressures over a long period of time are as capable of producing tissue damage as high pressures for a shorter period. Tissues can tolerate higher cyclic pressures compared with constant pressure. Pressures differ in various body positions. They are highest (70 mm Hg) on the buttocks in the lying position and in the sitting position can be as high as 300 mm Hg over the ischial tuberosities. These levels are well above the normal capillary closing pressures and are capable of causing tissue ischemia. If tissues have been compressed for prolonged periods, tissue damage will continue to occur even after the pressure is relieved. This continued tissue damage relates to changes at the cellular level that lead to difficulties with restoration of perfusion. Initial skin breakdown can occur in 6 to 12 hours in healthy individuals and more quickly (less than 2 hours) in those who are debilitated.

More than 95% of all pressure ulcers develop over five classic locations: sacral/coccygeal area, greater trochanter, ischial tuberosity, heel, and lateral malleolus. Correct anatomical terminology is important when identifying the true location of the pressure ulcer. For example, many clinicians often document pressure ulcers as being located on the patient’s hip. The hip, or iliac crest, is actually an uncommon location for pressure ulceration. The iliac crest, located on the front of the body, is rarely subject to pressure forces. The area most clinicians are referring to is correctly termed the greater trochanter. The greater trochanter is the bony prominence located on the side of the body, just above the proximal, lateral aspect of the thigh, or “saddlebag” area. The majority of pressure ulcers occur on the lower half of the body. The location of the pressure ulcer may affect clinical interventions. For example, the patient with a pressure ulcer on the sacral/coccygeal area with concomitant urinary incontinence requires treatments that addresses the incontinence problem. Ulcers in the sacral/coccygeal area are also more at risk for friction and shearing damage due to the location of the wound. Figure 16–1 shows the correct anatomical terminology for pressure ulcer locations. Typical pressure ulcer locations for palliative care patients are the sacral/coccygeal area, trochanters, and heels. Patients with contractures are at special risk for pressure ulcer development due to the internal pressure of the bony prominence and the abnormal alignment of the body and its extremities. Institutionalized older adults with severe functional decline are particularly susceptible to contractures due to immobilization for extended periods of time in conjunction with limited efforts for maintenance of range of motion.

Risk Factors for Pressure Ulcers

Pressure ulcers are physical evidence of multiple causative influences. Factors that contribute to pressure ulcer development can be thought of as those that affect the pressure force over the bony prominence and those that affect the tolerance of the tissues to pressure.

Mobility, sensory loss, and activity level are related to the concept of increasing pressure. Extrinsic factors including shear, friction, and moisture, as well as intrinsic factors such as nutrition, age, and arteriolar pressure, relate to the concept of tissue tolerance. Several additional areas may influence pressure ulcer development, including emotional stress, temperature, smoking, and interstitial fluid flow.

Immobility

Immobility, inactivity, and decreased sensory perception affect the duration and intensity of the pressure over the bony prominence. Immobility or severely restricted mobility is the most important risk factor for all populations and a necessary condition for the development of pressure ulcers. Mobility is the state of being movable. The immobile patient cannot move, or facility or ease of movement is impaired. Closely related to immobility is limited activity.

Inactivity

Activity is the production of energy or motion and implies an action. Activity is often clinically described by the ability of the individual to ambulate and move about. Those persons who are bed- or chair-bound, and thus inactive, are more at risk for pressure ulcer development. A sudden change in activity level may signal significant change in health status and increased potential for pressure ulcer development.

Sensory Loss

Sensory loss places patients at risk for compression of tissues and pressure ulcer development, because the normal mechanism for translating pain messages from the tissues is dysfunctional. Patients with intact nervous system pathways feel continuous local pressure, become uncomfortable, and change their position before tissue ischemia occurs. Spinal cord–injured patients have a higher incidence and prevalence of pressure ulcers. Patients with paraplegia or quadriplegia are unable to sense increased pressure; if their body weight is not shifted, pressure ulceration develops. Likewise, patients with changes in mental status or functioning are at increased risk for pressure ulcer formation. They may not feel the discomfort from pressure, may not be alert enough to move spontaneously, may not remember to move, may be too confused to respond to commands to move, or may be physically unable to move. This risk factor is particularly evident in the palliative care population, in which individuals may be at the end of life, may not be alert enough to move spontaneously, or may be physically unable to move.

Shear

Extrinsic risk factors are those forces that make the tissues less tolerant of pressure. Extrinsic forces include shear, friction, and moisture. Whereas pressure acts perpendicularly to
cause ischemia, shear causes ischemia by displacing blood vessels laterally and thereby impeding blood flow to tissues.\textsuperscript{22–24} Shear is caused by the interplay of gravity and friction. Shear is a parallel force that stretches and twists tissues and blood vessels at the bony tissue interface; as such, it affects the deep blood vessels and deeper tissue structures. The most common example of shear is seen in the bed patient who is in a semisitting position with knees flexed and supported by pillows on the bed or by head-of-bed elevation. If the patient’s skeleton slides down toward the foot of the bed, the sacral skin may stay in place (with the help of friction against the bed linen). This produces stretching, pinching, and occlusion of the underlying vessels, resulting in ulcers with large areas of internal tissue damage and less damage at the skin surface.

Friction

Friction and moisture are not direct factors in pressure ulcer development, but they have been identified as contributing to the problem by reducing tolerance of tissues to pressure.\textsuperscript{24} Friction occurs when two surfaces move across one another. Friction acts on tissue tolerance to pressure by abrading and damaging the epidermal and upper dermal layers of the skin. Additionally, friction acts with gravity to cause shear. Friction abrades the epidermis, which may lead to pressure ulcer development by increasing the skin’s susceptibility to pressure injury. Pressure combined with friction produces ulcerations at lower pressures than does pressure alone.\textsuperscript{24} Friction acts in conjunction with shear to contribute to the development of sacral/coccygeal pressure ulcers on patients in the semi-Fowler position.
Moisture

Moisture contributes to pressure ulcer development by removing oils on the skin, making it more friable, as well as interacting with body support surface friction. Constant moisture on the skin leads to maceration of the tissues. Waterlogging leads to softening of the skin’s connective tissues. Macerated tissues are more prone to erosion, and once the epidermis is eroded, there is increased likelihood of further tissue breakdown. 

Moisture alters the resiliency of the epidermis to external forces. Both shearing force and friction increase in the presence of mild to moderate moisture. Excess moisture may be caused by wound drainage, diaphoresis, or fecal or urinary incontinence.

Incontinence

Urinary and fecal incontinence are common risk factors associated with pressure ulcer development. Incontinence contributes to pressure ulcer formation by creating excess moisture on the skin and by chemical damage to the skin. Fecal incontinence has the added detrimental effect of bacteria in the stool, which can contribute to infection as well as skin breakdown. Fecal incontinence is more significant as a risk factor for pressure ulceration because of the bacteria and enzymes in stool and their effects on the skin. Inadequately managed incontinence poses a significant risk factor for pressure ulcer development, and fecal incontinence is highly correlated with pressure ulcer development.

Nutritional Risk Factors

There is some disagreement concerning the major intrinsic risk factors affecting tissue tolerance to pressure. However, most studies identify nutritional status as playing a role in pressure ulcer development. Hypoalbuminemia, weight loss, cachexia, and malnutrition are commonly identified as risk factors predisposing patients to pressure ulcer development. Low serum albumin levels are associated with having a pressure ulcer and with developing a pressure ulcer.

Age

Age itself may be a risk factor for pressure ulcer development, with age-related changes in the skin and in wound healing increasing the risk of pressure ulcer development. The skin and support structures undergo changes in the aging process. There is a loss of muscle, a decrease in serum albumin levels, diminished inflammatory response, decreased elasticity, and reduced cohesion between dermis and epidermis. These changes combine with other changes related to aging to make the skin less tolerant of pressure forces, shear, and friction.

Medical Conditions and Psychological Factors

Certain medical conditions or disease states are also associated with pressure ulcer development. Orthopedic injuries, altered mental status, and spinal cord injury are such conditions. Other psychological factors may affect risk for pressure ulcer development. Self-concept, depression, and chronic emotional stress have been cited as factors in pressure ulcer development; and the emerging role of cortisol levels in pressure ulcer development bears monitoring.

Environmental Resources

Environmental resources include socioeconomic, psychosocial, health care system, and therapy resources. These factors are less understood than other risk factors; however, several of them play important roles in determining risk for pressure ulcer development and course of pressure ulcer care in patients receiving palliative care. Socioeconomic resources that may influence pressure ulcer development and healing are cost of therapy, type of payor (insurance type), and access to health care. In palliative care, cost of therapy becomes an important issue, particularly in long-term care facilities, where financial resources are limited and cost of therapy may hinder access to treatment.

Health care system resources are the type of health care setting and the experience, education level, and discipline of health care professionals. Patients receiving palliative care are often in long-term care facilities and dependent on the direct care practices of nurse aides with minimal education in health care, nursing, and, especially, the needs of the palliative care patient. Therapy resources include topical treatments for wounds and systemic treatments. Palliative care patients often receive concomitant therapy that impairs mobility or sensory perception (e.g., pain medication) or normal healing mechanisms (e.g., steroids).

Psychosocial resources include adherence to the therapy plan, cultural values and beliefs, social support network (family and caregiver support), spiritual support, and alternative medicine use. The social support network is a key factor for palliative care. Patients receiving palliative care are often cared for in the home or in a long-term care facility. Home caregivers may be family members of the patient, often the spouse or significant other. If the patient is older and frail, it is typical to find that the caregiver is also older and frail, yet responsible for providing direct care 24 hours a day with minimal respite or support. Many times the nurse is dealing with two patients, the patient receiving palliative care and the patient’s caregiver, who may also be frail and in need of services. The family member may be physically unable to reposition the patient or to provide other care services. In long-term care facilities, the problem may not be physical inability to perform the tasks but lack of time or motivation. The availability of nurse attendants in the long-term care facility may be such that turning and repositioning of palliative care patients are not high-priority tasks.

In summary, environmental resources are not all well defined and typically are not included in formal risk-assessment tools for development of pressure ulcers. However, the importance of environmental resources in both the development and healing of pressure ulcers is clinically relevant in palliative care.
Use of Risk-Assessment Scales

For practitioners to intervene in a cost-effective way, a method of screening for risk factors is necessary. Several risk-assessment instruments are available to clinicians. Screening tools assist in prevention by distinguishing those persons who are at risk for pressure ulcer development from those who are not. The only purpose in identifying patients who are at risk for pressure ulcer development is to allow for appropriate use of resources for prevention. The use of a risk-assessment tool allows for targeting of interventions to specific risk factors for individual patients. The risk-assessment instrument selected is based on its reliability for the intended raters, its predictive validity for the population, its sensitivity and specificity under consideration, and its ease of use including the time required for completion. The most common risk-assessment tools are Braden’s Scale for Predicting Pressure Sore Risk and Norton’s Scale. There is minimal information on the use of either instrument in palliative care patients, but both tools have been used in long-term care facilities, where many patients are assumed to be receiving palliative care. This is an area in which further study is warranted.

Norton’s Scale. The Norton tool is the oldest risk-assessment instrument. Developed in 1961, it consists of five subscales: physical condition, mental state, activity, mobility, and incontinence. Each parameter is rated on a scale of 1 to 4, with the sum of the ratings for all five parameters yielding a total score ranging from 5 to 20. Lower scores indicate increased risk, with scores of 16 or lower indicating “onset of risk” and scores of 12 or lower indicating high risk for pressure ulcer formation.

Braden Scale for Predicting Pressure Sores. The Braden Scale was developed in 1987 and is composed of six subscales that conceptually reflect degrees of sensory perception, moisture, activity, nutrition, friction and shear, and mobility. All subscales are rated from 1 to 4, except for friction and shear, which is rated from 1 to 3. The subscales may be summed for a total score ranging from 6 to 23.

Lower scores indicate lower function and higher risk for development of a pressure ulcer. The cutoff score for hospitalized adults is considered to be 16, with scores of 16 and lower indicating at-risk status. In older patients, some have found cutoff scores of 17 or 18 to be better predictors of risk status. Levels of risk are based on the predictive value of a positive test. Scores of 15 to 16 indicate mild risk, with a 50% to 60% chance of developing a stage I pressure ulcer; scores of 12 to 14 indicate moderate risk, with 65% to 90% chance of developing a stage I or II lesion; and scores lower than 12 indicate high risk, with a 90% to 100% chance of developing a stage II or deeper pressure ulcer. The Braden Scale has been tested in acute care and long-term care with several levels of nurse raters and demonstrates high interrater reliability with registered nurses.

Validity has been established by expert opinion, and predictive validity has been studied in several acute care settings, with good sensitivity and specificity demonstrated. The Braden Scale is the model used in this chapter for prevention of pressure ulcers in patients requiring palliative care.

Regardless of the instrument chosen to evaluate risk status, the clinical relevance is threefold. First, assessment for risk status must occur at frequent intervals. Assessment should be performed at admission to the health care organization (within 24 hours), at predetermined intervals (usually weekly), and whenever a significant change occurs in the patient’s general health and status. The second clinical implication is the targeting of specific prevention strategies to identified risk factors. The final clinical implication is for those patients in whom prevention is not successful. For patients with an actual pressure ulcer, the continued monitoring of risk status may prevent further tissue trauma at the wound site and development of additional wound sites.

Prevention of Pressure Ulcers

Prevention strategies are targeted at reducing risk factors and can be focused on eliminating specific risk factors. Early intervention for pressure ulcers is risk factor specific and prophylactic in nature. The prevention strategies are presented here by risk factor, beginning with general information and ending with specific strategies to eliminate particular risk factors. Prevention is a key element for palliative care. If pressure ulcers can be prevented, the patient is spared tiresome, sometimes painful, and often overwhelming treatment. The Braden Scale is the basis for these prevention interventions. Prevention interventions that are appropriate to the patient’s level of risk and specific to individual risk factors should be instituted. For example, the risk factor of immobility is managed very differently for the comatose patient compared with the patient with severe pain on movement or the patient who is still mobile even if bed bound. The comatose patient requires caregiver education and caregiver-dependent repositioning. The patient with severe pain on movement requires special support surface intervention and minimal movement methods with a foam wedge. The patient who is still mobile but bed bound requires self-care education and may be able to perform self-repositioning. The interventions for the risk factor of immobility are very different for these patients.

Immobility, Inactivity, and Sensory Loss

Patients who have impaired ability to reposition and who cannot independently change body positions must have local pressure alleviated by any of the following: passive repositioning by caregivers, pillow bridging, or pressure relief or reduction support surfaces for bed and chair. In addition, measures to increase mobility and activity and to decrease friction and shear should be instituted. This is true for persons receiving palliative care until the terminal stage of the disease process. The difference for those receiving palliative care is the
emphasize on providing adequate pain management as part of prevention interventions related to movement and repositioning.

Overhead bed frames with trapeze bars are helpful for patients with upper body strength and may increase mobility and independence with body repositioning. Wheelchair-bound patients with upper body strength can be taught and encouraged to do wheelchair pushups to relieve pressure and allow for reperfusion of the tissues in the ischial tuberosity region. For patients who are weak from prolonged inactivity, providing support and assistance for reconditioning and increasing strength and endurance may help prevent further decline. Mobility plans for each patient should be individualized, with the goal of attaining the highest level of mobility and activity possible in light of the goals of overall care. Caregivers in the home are often left to fend for themselves for prevention interventions and may be frail and have health problems themselves. A return demonstration of a repositioning procedure can be very informative to the nurse. The nurse may need to coach, improvise, and think of creative strategies for caregivers to use in the home setting to meet the patient’s needs for movement and tissue reperfusion.

Passive Repositioning by Caregiver. Turning schedules and passive repositioning by caregivers is the normal intervention response for patients with immobility risk factors. Typically, turning schedules are based on time or event. If time-based, turning is usually done every 2 hours for full-body change of position and more often for small shifts in position. Event-based schedules relate to typical events during the day (e.g., turning the patient after each meal). Full-body change of position involves turning the patient to a new lying position, such as from the right side-lying position to the left side-lying position or the supine position. If the side-lying position is used in bed, avoidance of direct pressure on the trochanter is essential. To avoid placing pressure on the trochanter, the patient is placed in a 30-degree, laterally inclined position instead of the commonly used 90-degree side-lying position, which increases tissue compression over the trochanter. The 30-degree, laterally inclined position allows for distribution of pressure over a greater area. Small shifts in position involve moving the patient but keeping the same lying position, such as changing the angle of the right side-lying position or changing the position of the lower extremities in the right side-lying position. Both strategies are helpful in achieving reperfusion of compressed tissues, but only a full-body change of position completely relieves pressure.

A foam wedge is very useful in positioning for frail caregivers and for patients with severe pain on movement. The foam wedge should provide a 30-degree angle of lift when fully inserted behind the patient, usually extending from the shoulders to the hips/buttocks. Once it is in place, even the most frail of caregivers can easily pull the wedge out slightly every hour, providing for small shifts in position and tissue reperfusion. Even patients with pain on movement find the slight movement from the foam wedge tolerable. There are other techniques to make turning patients easier and less time-consuming. Turning sheets, draw sheets, and pillows are essential for passive movement of patients in bed. Turning sheets are useful in repositioning the patient to a side-lying position. Draw sheets are used for pulling patients up in bed; they help prevent dragging of the patient's skin over the bed surface.

The recommended time interval for a full change of position is every 2 hours, depending on the individual patient profile. Similar approaches to repositioning are useful for patients in chairs. Full-body change of position involves standing the patient and then re-sitting the patient in a chair. Small shifts in position for those in chairs might involve changing the position of the lower extremities or inserting a small foam pillow or wedge. For the chair-bound patient, it is also helpful to use a foot stool to help reduce the pressure on the ischial tuberosities and to distribute the pressure over a wider surface. Attention to proper alignment and posture is essential. Individuals at risk for pressure ulcer development should avoid uninterrupted sitting in chairs, and clinical practice guidelines suggest repositioning every hour. The rationale behind the shorter time frame is the extremely high pressures generated on the ischial tuberosities in the seated position. Those patients with upper-body strength should be taught to shift weight every 15 minutes, to allow for tissue reperfusion. Again, pillows may be used to help position the patient in proper body alignment. Physical therapy and occupational therapy can assist in body-alignment strategies with even the most contracted patient.

In many instances, patients receiving palliative care at home spend much of their time up in recliner chairs. The ability of recliner chairs to provide a pressure-reduction support surface is not known, and individual recliner chairs probably have various levels of pressure-reducing capability. Therefore, it is still prudent to institute a repositioning schedule for those using recliner chairs. Repositioning of patients in recliner chairs is more difficult due to the physical properties of the chair and requires some creativity. The repositioning schedule should mimic the schedule for those in wheelchairs.

For patients with significant pain on movement, premedication 20 to 30 minutes before a scheduled large position change may make routine repositioning more acceptable for the patient and the family. In those close to death, repositioning schedules may be used solely for maintaining comfort, with few or no attempts to reposition as a strategy for preventing skin problems.

Pillow Bridging. Pillow bridging involves the use of pillows to position patients with minimal tissue compression. The use of pillows can help prevent pressure ulcers from occurring on the medial knees, the medial malleolus, and the heels. Pillows should be placed between the knees, between the ankles, and under the heels.

Pillow use is especially important for reducing the risk of development of heel ulcers regardless of the support surface in use. The best prevention strategy for eliminating pressure ulcers on the heels is to keep the heels off the surface of the bed. Use of pillows under the lower extremities keeps the heel
from making contact with the support surface of the bed. Pillows help to redistribute the pressure over a larger area, thus reducing high pressures in one specific area. The pillows should extend and support the leg from the groin or perineal area to the ankle. Use of donut-type or ring cushion devices is contraindicated. Donut ring cushions cause venous congestion and edema and actually increase pressure to the area of concern.18

Use of Pressure Relief and Pressure-Reduction Support Surfaces. There are specific guidelines for the use of support surfaces to prevent and manage pressure ulcers.42–44 Regardless of the type of support surface in use, written repositioning and turning schedules remain essential. Support surfaces serve as adjuncts to strategies for positioning and careful monitoring of patients. The type of support surface chosen is based on a multitude of factors, including clinical condition of the patient, type of care setting, ease of use, maintenance, cost, and characteristics of the support surface. The primary concern should be the therapeutic benefit to the palliative care patient. Table 16A–1 categorizes the types of support surfaces available and their general performance characteristics.42

Pressure-Reducing Support Surfaces. Pressure-reduction devices lower tissue interface pressures but do not consistently maintain interface pressures below capillary closing pressures in all positions on all body locations. Pressure-reducing support surfaces are indicated for patients who are at risk for pressure ulcer development, who can be turned, and who have skin breakdown involving only one sleep surface.18,19 Patients with an existing pressure ulcer who are at risk for development of further skin breakdown should be managed on a pressure-reducing support surface.

Pressure-reduction devices can be classified as static or dynamic. Static devices do not move; they reduce pressure by spreading the load over a larger area. A simple definition of a static support surface is one that does not require electricity to function, usually a mattress overlay (which is placed on top of the standard hospital mattress). Examples of static devices are foam, air, or gel mattress overlays and water-filled mattresses. The difficulties with foam devices include retaining moisture and heat and not reducing shear. Air and water static devices also have difficulties associated with retaining moisture and heat.

Dynamic support surfaces move. A simple definition of a dynamic support surface is one that requires a motor or pump and electricity to operate. One example is the alternating-pressure air mattress. Most of these devices use an electric pump to alternately inflate and deflate air cells or air columns, thus the term “alternating-pressure air mattress.” The key to determining effectiveness is the length of time over which cycles of inflation and deflation occur. Dynamic support surfaces may also have difficulties with moisture retention and heat accumulation.42 Dynamic devices may be preferable for palliative care patients, especially those with significant pain on movement, because they may help with tissue reperfusion when patients cannot be turned because of pain. When using pressure-reduction devices, the caregiver must ensure that the device is functioning properly and that the patient is receiving pressure reduction.

One concern when using mattress overlays, whether they are static or dynamic, is the “bottoming-out” phenomenon. Bottoming-out occurs when the patient’s body sinks down, the support surface is compressed beyond function, and the patient’s body lies directly on the hospital mattress. When bottoming-out occurs, there is no pressure reduction for the bony prominence of concern. Bottoming-out typically happens when the patient is placed on a static air mattress overlay that is not appropriately filled with air or when the patient has been on a foam mattress for extended periods. The nurse can monitor for bottoming-out by inserting a flat, outstretched hand between the overlay and the patient’s body part at risk. If the caregiver feels less than an inch of support material, the patient has bottomed-out. It is important to check for bottoming-out when the patient is in various body positions.

and to check at various body sites. For example, when the patient is lying supine, check the sacral/coccygeal area and the heels; and when the patient is side-lying, check the trochanter and lateral malleolus.\(^2\)

**Pressure-Relieving Support Surfaces.** Pressure-relief devices consistently reduce tissue interface pressures to a level below capillary closing pressure in any position and in most body locations. Pressure-relief devices are indicated for patients who are at high risk for pressure ulcer development and who cannot turn independently or have skin breakdown involving more than one body surface. Most commonly, pressure-relief devices are grouped into low air loss, fluidized air or high air loss, and kinetic devices. These devices often assist with pain control as well as relieving pressure.

Low air loss therapy devices use a bed frame with a series of connected air-filled pillows with surface fabrics of low-friction material. The amount of pressure in each pillow can be controlled and calibrated to provide maximal pressure relief for the individual patient. These devices provide pressure relief in any position, and most models have built-in scales. Low air loss therapy devices that are placed on top of standard hospital mattresses may be of particular benefit for palliative care patients at home.

Fluidized air or high air loss therapy devices consist of bed frames containing silicone-coated glass beads and incorporate both air and fluid support. The beads become fluid when air is pumped through the device, making them behave like a liquid. High air loss therapy has bactericidal properties due to the alkalinity of the beads (pH 10), the temperature, and entrapment of microorganisms by the beads. High air loss therapy relieves pressure and reduces friction, shear, and moisture (due to the drying effect of the bed). These devices cause difficulties when transferring patients because of the bed frame. The increased airflow can increase evaporative fluid loss, leading to dehydration. Finally, if the patient is able to sit up, a foam wedge may be required, limiting the beneficial effects of the bed on the upper back. In palliative care cases, use of high air loss therapy is typically not indicated for pressure ulcers alone but may be indicated for patients with significant pain as well as pressure ulcers.

**Support Surface Selection.** Determining which support surface is best for a particular patient can be confusing. The primary concern must always be the effectiveness of the surface for the individual patient’s needs. The Agency for Healthcare Research and Quality (AHRQ, formerly Agency for Health Care Policy and Research [AHCPR]) recommends the following criteria as guidelines for determining how to manage tissue loading and support surface selection.\(^1\)

1. Assess all patients with existing pressure ulcers to determine their risk for developing additional pressure ulcers. If the patient remains at risk, use a pressure-reducing surface.
2. Use a static support surface if the patient can assume a variety of positions without bearing weight on an existing pressure ulcer and without “bottoming-out.”
3. Use a dynamic support surface if the patient cannot assume a variety of positions without bearing weight on an existing pressure ulcer, if the patient fully compresses the static support surface, or if the pressure ulcer does not show evidence of healing.
4. If a patient has large stage III or stage IV pressure ulcers on multiple turning surfaces, a low air loss bed or a fluidized air (high air loss) bed may be indicated.
5. If excessive moisture on intact skin is a potential source of maceration and skin breakdown, a support surface that provides airflow can be important in drying the skin and preventing additional pressure ulcers.
6. Any individual who is at risk for developing pressure ulcers should be placed on a static or dynamic pressure-reducing support surface.

**Seating Support Surfaces.** Support surfaces for chairs and wheelchairs can be categorized similarly to support surfaces for beds. In general, providing adequate pressure relief for chair-bound or wheelchair-bound patients is critical. The patient at risk for pressure ulcer formation is at increased risk in the seated position because of the high pressures across the ischial tuberosities. Most pressure-reducing devices for chairs are static overlays, such as those made out of foam, gel, air, or some combination. Positioning of chair- or wheelchair-bound individuals must include consideration of individual anatomy and body contours, postural alignment, distribution of weight, balance, and stability in addition to pressure relief.

**Reducing Friction and Shear**

Measures to reduce friction and shear relate to passive or active movement of the patient. To reduce friction, several interventions are appropriate. Providing topical preparations to eliminate or reduce the surface tension between the skin and the bed linen or support surface assists in reducing friction-related injury. To lessen friction-induced skin breakdown, appropriate techniques must be used when moving patients so that skin is never dragged across the linens. Patients who exhibit voluntary or involuntary repetitive body movements (particularly movements of the heels or elbows) require stronger interventions. Use of a protective film such as a transparent film dressing or a skin sealant, a protective dressing such as a thin hydrocolloid, or protective padding helps to eliminate the surface contact of the area and decrease the friction between the skin and the linens.\(^1\) Even though heel, ankle, and elbow protectors do nothing to reduce or relieve pressure, they can be effective aids against friction.

Most shear injury can be eliminated by proper positioning, such as avoidance of the semi-Fowler position and limited use of upright positions (i.e., positions more than 30 degrees inclined). Avoidance of upright positions may prevent sliding- and shear-related injuries. Use of foot boards and knee Gatch...
(or pillows under the lower leg) to prevent sliding and to maintain position is also helpful in reducing shear effects on the skin. Observation of the patient when sitting is also important, because the patient who slides out of the chair is at equally high risk for shear injury. Use of footstools and the foot pedals on wheelchairs, together with appropriate 90-degree flexion of the hip (which may be achieved with the use of pillows, special seat cushions, or orthotic devices) can help prevent chair sliding.

**Nutrition**

Nutrition is an important element in maintaining healthy skin and tissues. There is a strong relationship between nutrition and pressure ulcer development.29 The severity of pressure ulceration is also correlated with severity of nutritional deficits, especially low protein intake and low serum albumin levels.28,30,31 Nutritional assessment is key in determining the appropriate interventions for the patient. A short nutritional assessment should be performed at routine intervals on all patients who are determined to be at risk for pressure ulcer formation.

Malnutrition may be diagnosed if the serum albumin level is lower than 3.5 mg/dL, the total lymphocyte count is less than 1800 cells/mm³, or body weight has decreased by more than 15%.42 Malnutrition impairs the immune system, and total lymphocyte counts are a reflection of immune competence. If the patient is diagnosed as malnourished, nutritional supplementation should be instituted to help achieve a positive nitrogen balance. Examples of oral supplements are assisted oral feedings and dietary supplements. Tube feedings have not been effective for patients with pressure ulcers. The goal of care is to provide approximately 30 to 35 calories per kilogram of weight per day and 1.25 to 1.5 g of protein per kilogram of weight per day.42 It may be difficult for a pressure ulcer patient or an at-risk patient to ingest enough protein and calories necessary to maintain skin and tissue health. Oral supplements can be very helpful in boosting calorie and protein intake, but they are designed only to be an adjunct to regular oral intake. Monitoring of nutritional indices is helpful to determine the effectiveness of the care plan. Serum albumin, protein markers, body weight, and nutritional assessment should be performed every 3 months to monitor for changes in nutritional status if appropriate.

In palliative care, nutrition can be a major risk factor for pressure ulcer development. Nutritional supplementation may not be possible in all cases; however, if the patient can tolerate it, supplementation should be encouraged if it is in keeping with the overall goals of care. Involvement of a dietitian during the early assessment of the patient is important to the overall success of the plan. Maintenance of adequate nutrition to prevent pressure ulcer development and to repair existing pressure ulcers in palliative care patients is fraught with differing opinions. The issue is how to balance nutritional needs for skin care without providing artificial nutrition to prolong life. One of the problems in this area is the limited research available. The inadequate evidence base leaves clinicians to rely on expert opinion and their own clinical experience. Perhaps the best advice is to look at the whole clinical picture rather than focusing only on the wound. Viewing the pressure ulcer as a part of the whole, within the contextual circumstances of the patient, should provide some assistance in determining how aggressive to be in providing nutrition. The overriding concern in palliative care is to provide for comfort and to minimize symptoms. If providing supplemental nutrition aids in providing comfort to the patient and is mutually agreed upon by the patient, family caregivers, and health care provider, then supplemental nutrition (in any form) is very appropriate for palliative wound care. If the patient’s condition is such that to provide supplemental nutrition (in any form) increases discomfort and the prognosis is expected to be poor and rapid, then providing supplemental nutrition should not be a concern and is not appropriate for palliative wound care. It is important to remember that little evidence exists for either of these viewpoints, yet expert opinions on the topic abound.

**Managing Moisture**

The preventive interventions related to moisture include general skin care, accurate diagnosis of incontinence type, and appropriate incontinence management.

**General Skin Care.** General skin care involves routine skin care, accurate diagnosis of incontinence type, and appropriate incontinence management.

**Incontinence Management.** Volumes have been written about various incontinence management techniques. This discussion is meant to serve as a stepping stone to those resources available to clinicians concerning management of incontinence. It does not include all management strategies and only briefly mentions several strategies that are most pertinent to palliative care patients at high risk of development of pressure ulcers. Management of incontinence is dependent on assessment and diagnosis of the problem (see Chapter 14).

**Incontinence Assessment.** Assessment of incontinence should include history of the incontinence, including patterns of elimination, characteristics of the urinary stream or fecal mass, and sensation of bladder or rectal filling. The physical examination is designed to gather specific information related to bladder or rectal functioning and therefore is limited in scope. A limited neurological examination should provide data on the mental status and motivation of the patient and caregiver, specific motor skills, and condition of back and lower extremities. The genitalia and perineal skin are assessed for signs of perineal skin lesions and perineal sensation.
Palliative care patients with incontinence need management strategies. Baseline data can identify patients at risk for behavioral management strategies for incontinence. Incontinence in palliative care patients may be successfully managed with scheduled toileting. Scheduled toileting is caregiver dependent and requires a motivated caregiver to be successful. Adequate fluid intake is an important component of a scheduled toileting program.

Scheduled toileting, or habit training, is toileting at planned time intervals. The goal is to keep the patient dry by assisting him or her to void at regular intervals. There can be attempts to match the interval to the individual patient’s natural voiding schedule. There is no systematic effort to motivate patients to delay voiding or to resist the urge to void. Scheduled toileting may be based on the clock (e.g., toileting every 2 hours) or on activities (e.g., toileting after meals and before transferring to bed).

Underpads and briefs may be used to protect the skin of patients who are incontinent of urine or stool. These products are designed to absorb moisture, wick the wetness away from the skin, and maintain a quick-drying interface with the skin. Studies in both infants and adults demonstrate that products that are designed to present a quick-drying surface to the skin and to absorb moisture do keep the skin drier and are associated with a lower incidence of dermatitis. The critical feature is the ability to absorb moisture and present a quick-drying surface, not whether the product is disposable or reusable. Regardless of the product chosen, containment strategies imply the need for a check-and-change schedule for the incontinent patient, so that wet linens and pads may be removed in a timely manner. Underpads are not as tight or constricting as briefs. Kemp suggested alternating use of underpads and briefs. This recommendation echoes the early work of Willis, who studied warm-water immersion syndrome and found that the effects of water on the skin could be diminished by allowing the skin to dry out between wet periods. Use of briefs when the patient is up in a chair, ambulating, or visiting and use of underpads when the patient is in bed is one suggestion for combining the strengths of both products.

External collection devices may be more effective with male patients. External catheters or condom catheters are devices applied to the shaft of the penis that direct the urine away from the body and into a collection device. Newer models of external catheters are self-adhesive and easy to apply. For patients with a retracted penis, a special pouching system, similar to an ostomy pouch, is available. A key concern with the use of external collection devices is routine removal of the product for inspection and hygiene of the skin.

There are special containment devices for fecal incontinence as well. Fecal incontinence collectors consist of a self-adhesive skin barrier attached to a drainable pouch. Application of the device is somewhat dependent on the skill of the clinician. To facilitate success, the patient should be put on a routine for changing the pouch before leakage occurs. The skin barrier provides a physical obstacle to keep the stool away from the skin and helps to prevent dermatitis and associated skin problems. Skin barrier wafers without an attached pouch can be useful in protecting the skin from feces or urine.

Use of moisturizers for dry skin and use of lubricants for reduction of friction injuries are also recommended skin care strategies. Moisture barriers are used to protect the skin from the effects of moisture. Although products that provide a moisture barrier are recommended, the reader is cautioned that the recommendation is derived from usual practice and clinical practice guidelines and is not research based. The success of the particular product is linked to how it is formulated and the hydrophobic properties of the product. Generally, pastes are thicker and more repellent of moisture than ointments. As a quick evaluation, one can observe the ease with which the product can be removed with water during routine cleansing: if the product comes off the skin with just routine cleansing, it probably is not an effective barrier to moisture. Mineral oil may be used for cleansing some of the heavier barrier products (e.g., zinc oxide paste) to ease removal from the skin.

**Pressure Ulcer Assessment**

The foundation for designing a palliative care plan for the patient with a pressure ulcer is a comprehensive assessment. Comprehensive assessment includes assessment of wound severity, wound status, and the total patient.

**Wound Severity**

Assessment of wound severity refers to the use of a classification system for diagnosing the severity of tissue trauma by determining the tissue layers involved in the wound. Classification systems such as staging pressure ulcers provide communication regarding wound severity and the tissue layers involved in the injury.

Pressure ulcers are commonly classified according to grading or staging systems based on the depth of tissue destruction. The National Pressure Ulcer Advisory Panel (NPUAP) recommended the use of a universal four-stage classification system to describe depth of tissue damage. Staging systems measure only one characteristic of the wound and should not be viewed as a complete assessment independent of other indicators. Staging systems are best used as a diagnostic tool for indicating wound severity. Table 16A–2 presents pressure ulcer staging criteria according to the NPUAP. Pressure-induced skin damage that manifests as purple, blue, or black areas of intact skin may represent deep tissue injury (DTI).
These lesions commonly occur on heels and the sacrum and signal more severe tissue damage below the skin surface. DTI lesions reflect tissue damage at the bony tissue interface and may progress rapidly to large tissue defects.

Wound Status

Pressure ulcer assessment is the base for maintaining and evaluating the therapeutic plan of care. Assessment of wound status involves evaluation of multiple wound characteristics. Initial assessment and follow-up assessments at regular intervals to monitor progress or deterioration of the sore are necessary to determine the effectiveness of the treatment plan. Adequate assessment is important even when the goal of care is comfort, not healing. The assessment data enable clinicians to communicate clearly about a patient’s pressure ulcer, provide for continuity in the plan of care, and allow evaluation of treatment modalities. Assessment of wound status should be performed weekly and whenever a significant change is noted in the wound. Assessment should not be confused with monitoring of the wound at each dressing change. Monitoring of the wound can be performed by less skilled caregivers, but assessment should be performed on a routine basis by health care practitioners. Use of a systematic approach with a comprehensive assessment tool is helpful.

There are few tools available that encompass multiple wound characteristics to evaluate overall wound status and healing. Two available tools are the Pressure Ulcer Scale for Healing (PUSH) and the Bates-Jensen Wound Assessment Tool (BWAT, revised Pressure Sore Status Tool).

The PUSH tool incorporates surface area measurements, exudate amount, and surface appearance. These wound characteristics were chosen based on principal component analysis to define the best model of healing. The clinician measures the size of the wound, calculates the surface area (length times width), and chooses the appropriate size category on the tool (0 to 10). Exudate is evaluated as none (0), light (1), moderate (2), or heavy (3). Tissue type choices include closed (0), epithelial tissue (1), granulation tissue (2), slough (3), and necrotic tissue (4). The three subscores are then summed for a total score.

Reliability testing of the tool with a large sample is under way. The PUSH tool may offer a quick assessment to predict healing outcomes. The PUSH tool is best used as a method of prediction of wound healing. Therefore, it may not be the best tool for palliative care patients, because healing is not an expected outcome of care. Assessment of additional wound characteristics may still be needed, to develop a treatment plan for the pressure ulcer. The BWAT includes additional wound characteristics that may be helpful in designing a plan of care for the wound.

The BWAT or Pressure Sore Status Tool (Figure 16A–2), developed in 1990 by Bates-Jensen and revised in 2001, evaluates 13 wound characteristics with a numerical rating scale and rates them from best to worst possible. The BWAT is recommended as a method of assessment and monitoring of
Complete the rating sheet to assess wound status. Evaluate each item by picking the response that best describes the wound and entering the score in the item score column for the appropriate date.

**TOTAL SCORE**

**SIGNATURE**

---

**WOUND STATUS CONTINUUM**

Plot the total score on the Wound Status Continuum by putting an "X" on the line and the date beneath the line. Plot multiple scores with their dates to see-at-a-glance regeneration or degeneration of the wound.

---

*Figure 16A.2. (continued)*
pressure ulcers and other wounds. It is a pencil-and-paper instrument comprising 15 items: location, shape, size, depth, edges, undermining or pockets, necrotic tissue type, necrotic tissue amount, exudate type, exudate amount, surrounding skin color, peripheral tissue edema, peripheral tissue induration, granulation tissue, and epithelialization. Two items, location and shape, are nonscored. The remaining 13 are scored items, and each appears with characteristic descriptors rated on a scale of 1 (best for that characteristic) to 5 (worst attribute of the characteristic). It is recommended that wounds be scored initially for a baseline assessment and at regular intervals to evaluate therapy. Once a lesion has been assessed for each item on the BWAT, the 13 item scores can be added to obtain a total score for the wound. The total score can then be monitored to determine “at a glance” the progress in healing or degeneration of the wound. Total scores range from 13 (skin intact but always at risk for further damage) to 65 (profound tissue degeneration). Appendix 16A–1 presents the instructions for use of the BWAT.

Reliability of the tool has been evaluated in an acute care setting with enterostomal therapy (ET) nurses (nurses with additional training in wound care)53 and in long-term care with a variety of health care professionals and one ET nurse expert in wound assessment.53 Interrater reliability ranged from \( r = 0.915 \) (\( P = 0.0001 \)) for the ET nurses53 to 0.78% agreement for the variety of health care professionals.52 The BWAT or the Pressure Sore Status Tool is the most widely used of the instruments available.

**Wound Characteristics**

Adequate initial wound assessment should encompass a composite of wound characteristics, which forms a base for differential diagnosis, therapeutic intervention, and future reassessment comparisons.52 The indices for wound assessment include all of the following: location, size of ulcer, depth of tissue involvement, stage or classification, condition of wound edges, presence of undermining or tunneling, necrotic tissue characteristics, exudate characteristics, surrounding tissue conditions, and wound healing characteristics of granulation tissue and epithelialization.54–58 Wound characteristics of concern for the palliative care patient include wound edges, undermining and tunneling, necrotic tissue characteristics, exudate characteristics, and surrounding tissue conditions. These five characteristics, as well as healing attributes of granulation tissue and epithelialization, are discussed in the following sections.

**Edges or Margins.** Wound edge, or margin, includes characteristics of distinctness, degree of attachment to the wound base, color, and thickness. In pressure ulcers, as tissues degenerate, broad and indistinct areas, in which the wound edge is diffuse and difficult to observe, become shallow lesions with edges that are more distinct, thin, and separate. As tissue trauma from pressure progresses, the reaction intensifies with a thickening and rolling inward of the epidermis, so that the edge is well defined and sharply outlines the ulcer, with little or no evidence of new tissue growth. In long-standing pressure ulcers, fibrosis and scarring result from repeated injury and repair, with the edges hyperpigmented, indurated, and firm59 and possible impairment in the migratory ability of epithelial cells.60 Pressure ulcers in palliative care may show significant tissue damage, and the edges may indicate areas of full-thickness tissue loss with other areas of partial-thickness damage. In palliative care, pressure ulcers may be present for prolonged periods with no change in the wound; the wound edges often exhibit hemosiderin staining or hyperpigmentation in conjunction with their rolled-under and thickened appearance.

When assessing edges, the nurse should look at the clarity and distinctness of the wound outline. With edges that are indistinct and diffuse, there are areas in which the normal tissues blend into the wound bed and the edges are not clearly visible. Edges that are even with the skin surface and the wound base are attached to the base of the wound. This means that the wound is flat, with no appreciable depth. Well-defined edges, on the other hand, are clear and distinct and can be outlined easily on a transparent piece of plastic. Edges that are not attached to the base of the wound imply a wound with some depth of tissue involvement. A crater or bowl or boat shape indicates a wound with edges that are not attached to the wound base. The wound has walls or sides. There is depth to the wound.

As the wound ages, the edges become rolled under and thickened to palpation. The edge achieves a unique hyperpigmented coloring due to hemosiderin staining. The pigment turns a gray or brown color in both dark- and light-skinned persons. Long-standing wounds may continue to thicken, with scar tissue and fibrosis developing in the wound edge, causing the edge to feel hard, rigid, and indurated. The wound edges are evaluated by visual inspection and palpation.

**Undermining and Tunneling.** The terms undermining and tunneling refer to the loss of tissue underneath an intact skin surface. Undermining, or pocketing, usually involves a greater percentage of the wound margins and more shallower length, compared with tunneling. Undermining usually involves subcaneous tissues and follows the fascial planes next to the wound.

Wounds with undermining have more aerobic and anaerobic bacteria than do wounds that are in the process of healing with no undermining.61 The degree and amount of undermining indicate the severity of tissue necrosis. As subcaneous fat degenerates, wound pockets develop. Initially, deep fascia limits the depth of pocketing, encouraging more superficial internal spread of undermining. Once the fascia is penetrated, undermining of deeper tissues may proceed rapidly.59 Internal dimensions of wound undermining are commonly measured with the use of cotton-tipped applicators and gentle probing of the wound. There are also premeasured devices that can be inserted under the wound edge and advanced into the deeper tissues to aid in determination of the extent of undermining.
Undermining and wound pockets should be assessed by inserting a cotton-tipped applicator under the wound edge, advancing it as far as it will go without using undue force, raising the tip of the applicator so that it may be seen or felt on the surface of the skin, marking the surface with a pen, and measuring the distance from the mark on the skin to the edge of the wound. This process is continued all around the wound. Then the percentage of the wound involved is determined with the help of a transparent metric measuring guide with concentric circles divided into quadrants. Another noninvasive method of assessment of wound pockets is the use of ultrasound to evaluate the undermined tissues. Ultrasonography provides a visual picture of the impaired tissues and can be repeated to monitor for improvement.

**Necrotic Tissue Type and Amount.** Necrotic tissue characteristics of color, consistency, adherence, and amount present in the wound must be incorporated into wound assessment. As tissues die during wound development, they change in color, consistency, and adherence to the wound bed. The level and type of tissue death influence the clinical appearance of the necrotic tissue. For example, as subcutaneous fat tissues die, a collection of stringy, yellow slough is formed. As muscle tissues degenerate, the dead tissue may be more thick or tenacious.

The characteristic “necrotic tissue type” is a qualitative variable, with most clinicians using descriptions of clinical observations of a composite of factors as a method of assessment. The characteristics of color, consistency, and adherence are most often used to describe the type of necrosis. Color varies, as necrosis worsens, from white or gray nonviable tissue, to yellow slough, and finally to black eschar. Consistency refers to the cohesiveness of the debris (i.e., thin or thick, stringy or clumpy). Consistency also varies on a continuum as the necrotic area deepens and becomes more dehydrated.

The terms *slough* and *eschar* refer to different levels of necrosis and are described according to color and consistency. A slough is described as yellow (or tan) and as thin, mucinous, or stringy, whereas eschar is described as black, and as soft or hard; eschar represents full-thickness tissue destruction. *Adherence* refers to the adhesiveness of the debris to the wound bed and the ease with which the two may be separated. Necrotic tissue tends to become more adherent to the wound bed as the level of damage increases. Clinically, eschar is more firmly adherent than is yellow slough.

Necrotic tissue is assessed for color, consistency, and adherence to the wound bed. The predominant characteristic present in the wound should be chosen for assessment. Necrotic tissue type changes as it ages in the wound, as debridement occurs, and as further tissue trauma causes increased cellular death. Slough usually is nonadherent or loosely adherent to the healthy tissues of the wound bed. By definition, nonadherent tissue appears scattered throughout the wound; it appears as if the tissue could easily be removed with gauze. Loosely adherent tissue is attached to the wound bed; it is thick and stringy and may appear as clumps of debris attached to wound tissue.

**Eschar Signifies Deeper Tissue Damage.** Eschar may be black, gray, or brown in color. It is usually adherent or firmly adherent to the wound tissues and may be soggy, soft or hard, or leathery in texture. A soft, soggy eschar is usually strongly attached to the base of the wound but may be lifting from (and loose from) the edges of the wound. A hard, crusty eschar is strongly attached to the base and edges of the wound. Hard eschars are often mistaken for scabs. Sometimes nonviable tissue appears before a wound is apparent. This can be seen as a white or gray area on the surface of the skin. The area usually demarcates within a day or two, when the wound appears and interrupts the skin surface.

Necrotic tissue retards wound healing because it is a medium for bacterial growth and a physical obstacle to epidermal resurfacing, wound contraction, and granulation. The greater the amount of necrotic tissue present in the wound bed, the more severe the insult to the tissue and the longer the time required to heal the wound. The amount of necrotic tissue usually affects the amount of exudate from the wound and causes wound odor, both of which are distressing to the patient and to caregivers. Because of the amount of necrotic tissue present, modifications of treatment and debridement techniques may be made. The depth of the wound cannot be assessed in the presence of necrosis that blocks visualization of the total wound.

The amount of necrotic tissue present in the wound is one of the easier characteristics to assess. The nurse uses a transparent measuring guide with concentric circles divided into quadrants laying it over the wound. The percentage of necrosis present is judged by looking at each quadrant. The judgments from each quadrant are added to determine the total percentage of the wound involved. Alternatively, the length and width of the necrotic tissue may be measured to determine the surface area involved in the necrosis.

**Exudate Type and Amount.** Wound exudate (also known as wound fluid, wound drainage) is an important assessment feature, because the characteristics of the exudate help the clinician to diagnose signs of wound infection, to evaluate appropriateness of topical therapy, and to monitor wound healing. Wound infection retards wound healing and must be treated aggressively. Proper assessment of wound exudate is also important because it affirms the body’s brief, normal inflammatory response to tissue injury. Accurate assessment and diagnosis of wound exudate and infection are critical components of effective wound management. One of the main goals of palliative wound care is to prevent infection and to control exudate, because these conditions lead to discomfort from the wound.

The healthy wound normally has some evidence of moisture on its surface. Healthy wound fluid contains enzymes and growth factors, which may play a role in promoting reepithelialization of the wound and provide needed growth factors for all phases of wound repair. The moist environment produced by wound exudate allows efficient migration of epidermal cells and prevents wound desiccation and further injury.62,63

---

In pressure ulcers, increased exudate is a response to the inflammatory process or infection. Increased capillary permeability causes leakage of fluids and substrates into the injured tissue. When a wound is present, tissue fluid leaks out of the open tissue. This fluid normally is serous or serosanguineous.

In the infected wound, the exudate may thicken, become purulent in nature, and continue to be present in moderate to large amounts. Examples of exudate character changes in infected wounds are the presence of *Pseudomonas*, which produces a thick, malodorously sweet-smelling, green drainage, or *Proteus* infection, which may have an ammonia-like odor. Wounds with foul-smelling drainage are generally infected or filled with necrotic debris, and healing time is prolonged as tissue destruction progresses. Wounds with significant amounts of necrotic debris often have a thick, tenacious, opaque, purulent, malodorous drainage in moderate to copious amounts. True wound exudate must be differentiated from necrotic tissue that sloughs off the wound as a result of debridement efforts. Exudate from sloughing necrotic tissue is commonly attached to or connected with the necrotic debris; frequently, the only method of differentiation is adequate debridement of necrotic tissue from the wound site. Liquefied necrotic tissue occurs most often as a result of enzymatic or autolytic debridement. Often, removal of the necrotic tissue reduces the amount and changes the character of wound exudate.

Exudate should be assessed for the amount and type of drainage that occurs. The type and color of wound exudate vary depending on the degree of moisture in the wound and the organisms present. Characteristics used to examine exudate are color, consistency, adherence, distribution in the wound, and presence of odor.

Estimating the amount of exudate in the wound is difficult due to wound size variability and topical dressing types. One problem with assessment of exudate amount is the size of the wound. What might be considered a large amount of drainage for a smaller wound may be considered a small amount for a larger wound, making clinically meaningful assessment of exudate difficult.

Certain dressing types interact with or trap wound fluid to create or mimic certain characteristics of exudate, such as color and consistency of purulent drainage. For example, both hydrocolloid and alginate dressings mimic a purulent drainage on removal of the dressing. Preparation of the wound site for appropriate assessment involves removal of the wound dressing and cleansing with normal saline to remove dressing debris in the wound bed, followed by evaluation of the wound for true exudate.

Although it is not a part of exudate assessment, evaluation of the wound dressing provides the clinician with valuable data about the effectiveness of treatment. Evaluation of the percentage of the wound dressing involved with wound drainage during a specific time frame is helpful for clinical management that includes dressings beyond traditional gauze. In estimating the percentage of the dressing involved with the wound exudate, clinical judgment must be quantified by putting a number to visual assessment of the dressing. For example, the clinician might determine that 50% percent of the hydrocolloid dressing was involved with wound drainage over a 4-day wearing period. Based on the data, the clinician might quantify the judgment for this type of dressing, length of dressing wear time, and wound cause as being a “minimal” amount of exudate. Clinical judgment of the amount of wound drainage requires some experience with expected wound exudate output in relation to phase of wound healing and type of wound, as well as knowledge of absorptive capacity and normal wear time of topical dressings.

Certain characteristics of exudate indicate wound degeneration and infection. If signs of cellulitis (erythema or skin discoloration, edema, pain, induration, purulent drainage) are present at the wound site, the exudate amount may be copious and seropurulent or purulent in character. The amount of exudate remains high or increases, and the character may change to frank purulence, with further wound degeneration. Wound infection must be considered in these cases.

Pressure ulcers manifest with a variety of wound exudate types and amounts. In partial-thickness pressure ulcers, the wound exudate is most likely to be serous or serosanguineous in nature and to be present in minimal to moderate amounts. In clean full-thickness pressure ulcers, the wound exudate is similar, with minimal to moderate amounts of serous to serosanguineous exudate. As healing progresses in the clean full-thickness pressure ulcer, the character of the exudate changes; it may become bloody if the fragile capillary bed is disrupted, and it lessens in amount.

For full-thickness pressure ulcers with necrotic debris, wound exudate is dependent on the presence or absence of infection and the type of therapy instituted. Exudate may appear moderate to large but, in fact, is related to the amount of necrotic tissue present and to liquefaction of the debris in the wound. Typically, the necrotic full-thickness pressure ulcer manifests with serous to seropurulent wound exudate in moderate to large amounts. With appropriate treatment, the wound exudate amount may temporarily increase, as the character gradually assumes a serous nature.

**Surrounding Tissue Condition.** The tissues surrounding the wound should be assessed for color, induration, and edema. The tissues surrounding the wound are often the first indication of impending further tissue damage and are a key gauge of successful prevention strategies. Color of the surrounding skin may indicate further injury from pressure, friction, or shearing. The tissues within 4 cm of the wound edge should be assessed. Dark-skinned persons show the colors “bright red” and “dark red” as a deepening of normal skin color or a purple or blacker hue. As healing occurs in dark-skinned persons, the new skin is pink and may never darken. In both light- and dark-skinned patients, new epithelium must be differentiated from tissues that are erythematous. To assess for blanchability in light-skinned patients, the nurse presses firmly on the skin with a finger, then lifts the finger and looks for “blanching,” or sudden whitening, of the tissues followed by prompt return of color to the area. Nonblanchable erythema signals more severe tissue damage.
Edema in the surrounding tissues delays wound healing in the pressure ulcer. It is difficult for neoangiogenesis, or growth of new blood vessels into the wound, to occur in edematous tissues. Again, tissues within 4 cm of the wound edge are assessed. Nonpitting edema appears as skin that is shiny and taut, almost glistening. Pitting edema is identified by firmly pressing a finger down into the tissues and waiting for 5 seconds; on release of pressure, tissues fail to resume their previous position and an indentation appears. Crepitis is the accumulation of air or gas in tissues. The clinician should measure how far edema extends beyond the wound edges.

Induration is a sign of impending damage to the tissues. Along with skin-color changes, induration is an omen of further pressure-induced tissue trauma. Tissues within 4 cm of the wound edge are assessed. Induration is an abnormal firmness of tissues with margins. The nurse should palpate where the induration starts and where it ends by gently pinching the tissues. Induration results in an inability to pinch the tissues. Palpation proceeds from healthy tissue, moving toward the wound margins. It is usual to feel slight firmness at the wound edge itself. Normal tissues feel soft and spongy; induration feels hard and firm to the touch.

**Granulation Tissue and Epithelialization.** Granulation and epithelial tissues are markers of wound health. They signal the proliferative phase of wound healing and usually foreshadow wound closure. Granulation tissue is the growth of small blood vessels and connective tissue into the wound cavity. It is more observable in full-thickness wounds because of the tissue defect that occurs in such wounds. In partial-thickness wounds, granulation tissue may occur so quickly, and in concert with epithelialization, or skin resurfacing, that it is unobservable in most cases. The granulation tissue is healthy when it is bright, beefy-red; shiny; and granular with a velvety appearance. The tissue looks “bumpy” and may bleed easily. Unhealthy granulation tissue, resulting from poor vascular supply, appears pale pink or blanched to a dull, dusky red. Usually, the first layer of granulation tissue to be laid down in the wound is pale pink and, as the granulation tissue deepens and thickens, the color becomes bright, beefy red.

The percentage of the wound that is filled with granulation tissue and the color of the tissue are characteristics indicative of the health of the wound. The clinician makes a judgment as to what percent of the wound has been filled with granulation tissue. This is much easier if there is some past history with the wound. If the wound has been monitored by the same person over multiple observations, it is simple to judge the amount of granulation tissue present. If the initial observation was done by a different observer or if the data are not available, the clinician simply must use his or her best judgment to determine the amount of tissue present.

Partial-thickness wounds heal by epidermal resurfacing and regeneration. Epithelialization occurs via lateral migration at the wound edges and the base of hair follicles as epithelial cells proliferate and resurface the wound. Full-thickness wounds heal by scar formation: the tissue defect fills with granulation tissue, the edges contract, and the wound is resurfaced by epithelialization. Therefore, epithelialization may occur throughout the wound bed in partial-thickness wounds but only from the wound edges in full-thickness wounds.

Epithelialization can be assessed by evaluating the amount of the wound that is surrounded by new tissue and the distance to which new tissue extends into the wound base. Epithelialization appears as pink or red skin. Visualization of the new epithelium takes practice. A transparent measuring guide is used to help determine the percentage of wound involvement and the distance to which the epithelial tissue extends into the wound.

**Monitoring the Wound.** In palliative care, monitoring of the wound is important, to continue to meet the goals of comfort and reduction in wound pain and wound symptoms such as odor and exudate. Evaluation of wound characteristics at scheduled intervals allows the nurse to revise the treatment plan as appropriate and often provides an indication of the overall health of the patient. In many cases, the pressure ulcer worsens as death approaches and as the patient’s condition worsens. The skin may be the first organ to actually “fail,” with other systems following the downward trend. Progressive monitoring is also important to determine whether the treatment is effectively controlling odor, managing exudate, preventing infection, and minimizing pain—the goals of wound care during palliative care.

**Total Patient Assessment**

Comprehensive assessment includes assessment of the total patient as well as of wound severity and wound status. Generally, diagnosis and management of the wound are best accomplished within the context of the whole person. Comprehensive assessment includes a focused history and physical examination, attention to specific laboratory and diagnostic tests, and a pain assessment. Table 16A–3 presents an overview of assessment for the patient with a pressure ulcer.

It is important to obtain a focused history and physical examination as part of the initial assessment. The patient history determines which relevant systems reviews are needed in the physical examination. The goals for treatment and the direction of care (e.g., curative with a goal of wound closure, palliative with a goal of reduced wound pain) can be determined with, at a minimum, the following patient history information: reason for admission to care facility or agency; expectations and perceptions about wound healing; psychological, social, cultural, and economic history; presence of medical comorbidities; current wound status; and previous management strategies.

The systems review portion of the patient history and physical examination provides information on comorbidities that may impair wound healing. Specific comorbidities such as diabetes, vascular disease, and immunocompromise have been related to impaired healing. The individual’s capacity to heal may be limited by specific disease effects...
on tissue integrity and perfusion, patient mobility, nutrition, and risk for wound infection. Therefore, throughout the patient history, systems review, and physical examination, the clinician considers host factors that affect wound healing.

Specific laboratory and diagnostic tests in a comprehensive assessment include data on nutrition, glucose management, and tissue oxygenation and perfusion. Nutritional parameters typically include evaluation of serum albumin. Serum albumin is a measure of protein available for healing; a normal level is greater than 3.5 mg/dL. Clinicians should evaluate laboratory values such as arterial blood gases to assess tissue perfusion and oxygenation abilities. Review of laboratory values is

| Laboratory and diagnostic tests | Nutritional parameters: serum albumin  
Tissue perfusion: arterial blood gases, hemoglobin and hematocrit, blood glucose levels, glycosylated hemoglobin | Specific tests depend on individual patient | - Baseline or initially<br>- Every 3 months for nutritional markers, tissue perfusion markers<br>- If performing self-blood glucose monitoring, daily levels are helpful |
| Pain | Assess for wound pain before and during procedures and when no procedure is occurring | Use 0–10 point scale, with 0 = no pain and 10 = worst pain ever, and have patient state level of pain. For nonverbal patients, observe for grimacing, pulling away, crying out, or withdrawal | - Baseline or initially<br>- Every day as needed<br>- Before and during procedures such as dressing changes, debridement, or repositioning |
prudent to determine the level of diabetic control. Normal glucose levels are 80 mg/dL. Concentrations of 180 to 250 mg/dL or higher indicate that glucose levels are out of control. The nurse should look specifically for a fasting blood glucose concentration lower than 140 mg/dL and a glycosylated hemoglobin concentration (HgbA1C) lower than 7%. The HgbA1C helps to determine the level of glucose control the patient has had over the last 2 to 3 months.

The final aspect of the comprehensive assessment is pain assessment. Pain is thought to be an important factor in healing. Until recently, chronic wound pain was largely ignored as a cofactor in healing. Krasner proposed a chronic wound pain experience model and described the typical pain experiences for persons with chronic wounds in four categories: noncyclic acute wound pain (e.g., sharp debridement), cyclic acute wound pain (e.g., with daily dressings or repositioning), and chronic wound pain (e.g., persistent pain with no wound manipulation). Krasner suggested that the model is best used as a guide for assessment, intervention, and evaluation.

Wound pain is evaluated by having the patient rate the pain on a numerical scale from 0 to 10, with 0 equal to no pain and 10 equal to the worst pain ever felt, or by use of a visual analog scale. Patients who are nonverbal are observed for withdrawal, grimacing, crying out, or other nonverbal signs of pain. Pain assessments should be done before and during wound procedures, such as dressing changes or debridement, and also at times when the dressing is intact and no procedures are in progress. The patient or caregiver should be encouraged to keep a pain diary, because the data may be valuable in evaluating changes in wound pain over time. The focused history, physical examination, evaluation of laboratory and diagnostic data, and pain assessment provide the context for the wound itself and, along with wound severity and wound status assessment, the basis for pressure ulcer treatment. Total patient assessment should also encompass evaluation of treatment appropriateness in light of the overall condition of the patient and the goals of palliative care.

Pressure Ulcer Management

Pressure ulcer management can be based on clinical practice guidelines. Existing guidelines are helpful in developing a palliative care plan. The existing guidelines are broad based and general and, as such, form a good basis for wound care when the goal is comfort as well as when the goal is healing.

In the United States, most pressure ulcer care is based on the 1994 AHRQ algorithms for treatment. The guidelines present a general approach to use in developing a care plan for the patient with a pressure ulcer. Although they were published in 1994, the general principles of ulcer management remain the same. Pressure ulcer care is focused on nutritional assessment and support, management of tissue loads, and ulcer care, including management of bacterial colonization and infection. These general guidelines are also appropriate for palliative care.

Nutritional Support. Because many studies have linked malnutrition with pressure ulcers, adequate nutritional support is an important part of pressure ulcer management. Figure 16A–3 presents the nutritional assessment and support algorithm for pressure ulcer management from the AHRQ guidelines. The clinician must ensure that dietary intake is adequate in the patient with a pressure ulcer. Prevention of malnutrition reduces the patient’s risk for further tissue trauma related to pressure or impaired wound healing. As noted in the discussion of prevention, maintenance of adequate nutrition in the palliative care patient may not be possible.

Management of Tissue Loads. Management of tissue loads refers to care related to those with pressure ulcers who are at risk for development of additional pressure ulcers. Figure 16A–4 presents an algorithm for management of tissue loads with support surfaces algorithm. This is an important part of pressure ulcer treatment, because many individuals with a pressure ulcer are at risk for further pressure-induced tissue trauma. More information on support surfaces and management of tissue loads was presented in the earlier discussion of prevention of pressure ulcers. It is important to understand that the goal of managing tissue loads in the palliative care patient is to ease suffering and discomfort from the wound. Use of pressure-reduction devices, such as alternating air mattresses, is particularly appropriate for palliative care.

Ulcer Care: Debridement. Direct pressure ulcer care involves adequate debridement of necrotic material, management of bacterial colonization and infection, wound cleansing, and selection of topical dressings. Figure 16A–5 presents an algorithm for ulcer care.

Adequate debridement of necrotic tissue is necessary for wound healing. Necrotic debris in the wound bed forms an obstacle to healing and provides a medium for bacterial growth. The patient’s condition and the goals of care determine the method of debridement. Sharp, mechanical, enzymatic, or autolytic debridement techniques may be used if there is no urgent need for drainage or removal of devitalized material from the wound. In the presence of advancing cellulitis, sepsis, or large and adherent amounts of necrotic debris, sharp debridement should be performed. In palliative care, debridement is still important, because the removal of nonviable material decreases wound odor. In the case of the black eschar that forms on heels, debridement may not be necessary. Observation of the black heel with attention to the development of pathological signs such as erythema, drainage, odor, or bogginess of the tissues is necessary. If signs of erythema, drainage, odor, or bogginess appear, then the heel eschar must be debrided.

Mechanical debridement includes the use of wet-to-dry dressings at specific intervals, hydrotherapy, or wound irrigation. Of these three methods, wound irrigation is the most favorable for wound healing. Wet-to-dry dressings are not favorable because of the time and labor involved in performing the dressing technique correctly and the potential for pain. Wet-to-dry dressings are not recommended for palliative care.
because of the frequency of dressing changes and the increased potential for wound pain. Hydrotherapy or whirlpool treatments may be helpful for wounds with large amounts of necrotic debris adherent to healthy tissues. In these cases, hydrotherapy helps to loosen the material from the wound bed for easier removal with sharp debridement.

Enzymatic debridement is performed by applying a topical agent containing an enzyme that destroys necrotic tissue. Enzymatic debridement should be considered if the patient is not a candidate for sharp debridement or is in long-term care or home care. Enzymes may be used alone or in conjunction with other debridement techniques. Enzymatic debridement may be an appropriate method for palliative care, because the frequency of dressing changes is usually once a day and the method is easy to use in conjunction with periodic sharp debridement.

Autolytic debridement involves the use of moisture-retentive dressings to cover the wound and allow necrotic tissue to self-digest from enzymes normally found in wound fluid or exudate. Autolytic debridement may be used in conjunction with other debridement methods such as intermittent sharp debridement or wound irrigation. Again, autolytic debridement may be particularly effective for palliative care. Autolytic debridement has the added benefit of decreased frequency of dressing changes (typically every 3 to 5 days), so the suffering associated with dressing changes is diminished.

Ulcer Care: Bacterial Colonization and Infection. Open pressure ulcers are typically colonized with bacteria. In most cases, adequate debridement and wound cleansing prevent the bacterial colonization from proceeding to the point of clinical infection. Figure 16A–6 presents a preferred pathway for management of bacterial colonization and infection. Wound management can be enhanced in pressure ulcers by attention to debridement of necrotic debris and adequate wound cleansing. These two steps alone are often sufficient to prevent wound infection in pressure ulcers, because they remove the debris that supports bacterial growth. Prevention of infection is an
important goal for the palliative care patient. Use of prolonged silver-release topical dressings helps control wound surface bacteria and is effective against a broad range of pathogens, including methicillin-resistant Staphylococcus aureus (MRSA).

Identification of infection is best accomplished by clinical assessment. Routine swab cultures should not be used to identify infection in most pressure ulcers. Swab cultures simply reflect the bacterial contamination on the surface of the wound and may not truly identify the organisms causing tissue infection. The recommended technique for diagnosis of tissue infection in pressure ulcers is needle aspiration or tissue biopsy.42 An alternative method involves use of surface swabs. After cleansing the wound with normal saline to remove any dressing debris, the nurse swabs a 1 cm² area of the wound bed with the surface swab for 5 seconds, until tissue fluid is apparent on the swab, and then sends the swab directly to the laboratory. This technique may better reflect actual bacterial invasion of the wound tissues than standard swab methods do.

Use of topical antimicrobial solutions is not indicated for clean pressure ulcers. Indeed, most topical antimicrobial solutions are toxic to the fibroblast, which is the cell responsible for wound healing and may cause a burning sensation, adding to the patient’s discomfort. Topical antiseptics, such as povidone iodine, iodophor, sodium hypochlorite, hydrogen peroxide, and acetic acid, do not significantly reduce the number of bacteria in wound tissue; however, they do harm the healthy wound tissues.42 As such, these substances usually have no place in the treatment of clean pressure ulcers. In wounds filled with necrotic debris, antiseptic/antimicrobial solutions may be used for a short course of therapy (typically 2 weeks), to assist with surface bacteria and odor reduction, and then evaluated for further use.

**Ulcer Care: Wound Cleansing.** Wound cleansing assists healing because it removes necrotic tissue, excess wound exudate, and metabolic wastes from the wound bed. Wound healing is optimized and the potential for wound infection is decreased when wound cleansing is a part of the treatment plan for pressure ulcers. Wound cleansing involves the selection of a solution for cleansing and a method of delivering the solution to the wound. Routine wound cleansing should be accomplished with minimal trauma to the wound bed. Wounds...
should be cleansed initially and at each dressing change. Minimal force should be applied when using gauze, sponges, or cloth to clean the wound bed. Skin cleansers and antimicrobial solutions are not indicated as solutions for cleaning pressure ulcers because they destroy the healthy wound tissues and are toxic to the fibroblast cell. Normal saline is the preferred solution, because it is physiological and will not harm healing tissues.

When wound irrigation is used to cleanse wounds, the irrigation pressure should fall within the range of 4 to 15 pounds per square inch (psi). Higher pressures may drive bacteria deeper into wound tissues or cause additional wound trauma. A 35-mL syringe with a 19-gauge angiocatheter delivers saline at 8 psi and is an effective method for removing bacteria from the wound bed.

**Ulcer Care: Dressings.** In general, moisture-retentive wound dressings are the most appropriate type for pressure ulcers. For palliative care, they are the dressings of choice because of the decreased frequency of required changes (typically every 3 to 5 days). The goal of the wound dressing is to provide an environment that keeps the wound bed tissue moist and the surrounding intact skin dry. Use of moist wound healing dressings supports a better rate of healing than use of dry gauze dressings; more importantly in palliative care, moist wound healing dressings contain odor, absorb exudate, and minimize dressing change discomfort. Clinical judgment is needed to determine the best dressing for the wound. The appropriate dressing should keep the surrounding intact skin dry while controlling wound exudate and should provide a minimal amount of pain during dressing changes.

The clinician must be aware of the absorptive capacity and pain reduction properties of the major dressing types. In general, thin film dressings have no absorptive capacity and minimize pain by covering exposed nerve endings. Thin film dressings are adherent to the skin surrounding the wound and sometimes to the wound itself, making dressing removal more likely to be painful. Hydrocolloids, hydrogels, and foam dressings typically have a minimal to moderate absorptive capacity. Hydrocolloid dressings are occlusive and reduce pain by preventing exposure of the wound to air. They have adhesive properties and can cause pain if removed improperly. Foam dressings are moderately absorptive and nonadherent, resulting in reduced pain during dressing changes. Hydrogel dressings are cool and soothing and are particularly effective in wounds that induce a burning sensation. Hydrogel dressings are nonadherent, reducing wound pain during dressing changes. Calcium alginate dressings, alginate collagen dressings, and exudate absorbing beads, flakes, pastes, or powders absorb large amounts of drainage. Dressings with a large absorptive capacity reduce pain related to maceration of surrounding tissues and to pressure caused by the excess exudate. Calcium alginate dressings are nonadherent and are easily removed from the wound during dressing changes. Soft silicone dressings absorb minimal amounts of drainage but are nonadherent and reduce pain associated with dressing changes.

Wounds with small or minimal amounts of exudate can benefit from a variety of dressings, including hydrocolloids, hydrogels, thin film dressings, and foam dressings. Wounds with moderate amounts of exudate may require dressings with a higher absorptive capacity, such as hydrocolloids, foam dressings, hydrogel sheet dressings, or composite dressings (those including a combination of products, such as a thin film with a foam island in the center). Wounds with a large amount of drainage require dressings that are capable of absorbing it, such as calcium alginites, alginate collagen combinations, or specific beads, pastes, or powders designed to handle large amounts of drainage. Wounds with significant odor benefit from dressings formulated with charcoal, such as charcoal foam and dressings with a charcoal filter overlay.

If a wound shows a significant loss of tissue or if undermining or pockets are present, the wound cavities should be loosely filled with dressing to eliminate the potential for abscess formation. Eliminating the dead space helps to prevent premature wound closure with resulting abscess formation. Dressings such as calcium alginites, impregnated hydrogel gauze strips, or wound cavity fillers are useful for eliminating the dead space. Loose filling of the undermined areas also assists with exudate management, because these wounds tend to have large amounts of exudate.

Wounds in the sacral area require additional protection from stool or urine contamination. Because dressings near the anus may be difficult to maintain, the clinician must monitor dressings in this area more frequently. Some hydrocolloid dressings have been designed with specific shapes to improve their ability to stay in place over sacral/coccygeal wounds. Wound pain must be managed with the same attention given to choice of wound dressings. In general, pain that is moderate to severe should be managed pharmacologically (see Chapters 5 and 6). The pressure ulcer alone may not require continuous pharmacological analgesia, but medication before procedures is essential. Lower levels of pain may be manageable with appropriate wound dressing choice and topical wound analgesia. Techniques useful for noncyclic and cyclic wound pain associated with procedures (e.g., debridement, dressing changes) include use of distraction (e.g., talking to the patient while performing the procedure), allowing the patient to call a “time-out” during the procedure, allowing the patient to control and participate in the procedure, providing opioids and/or nonsteroidal anti-inflammatory drugs 30 minutes before the procedure and afterwards, and administering topical anesthetics or topical opioids using hydrogels as a transport media. The lidocaine patch 5% (Lidoderm) blocks sodium channels and has been approved for postherpetic neuralgia. It is effective for chronic neuropathic pain. Another option is EMLA cream (eutectic mixture of lidocaine 5% and prilocaine 2.5%), which reduces debridement pain scores and might have a vasoactive effect cutaneously. Low-dose topical morphine was been used successfully in two small pilot studies to control pressure ulcer–related pain.

As evidenced by this discussion, attention to multiple wound characteristics helps to determine the most appropriate wound.
dressing. Evaluation of wound characteristics in follow-along assessments provides the basis for changes in topical dressings. For example, a wound that is heavily exudative may be treated topically with a calcium alginate dressing for several weeks; as the amount of wound exudate decreases, the wound dressing may appear dry at dressing changes. This indicates that use of a dressing with high absorptive capacity may not be needed any longer, and the wound dressing can be changed to one with minimal to moderate absorptive capacity, such as a hydrocolloid dressing. As the wound continues to heal and wound exudate becomes minimal or nonexistent, a thin film dressing may be used to provide protection from the environment.

**Patient and Caregiver Teaching Guidelines**

Patient and caregiver instruction in self-care must be individualized according to specific pressure ulcer development risk factors, individual learning styles and coping mechanisms, and the ability of the patient or caregiver to perform procedures. In teaching prevention guidelines to caregivers, it is particularly important to use return demonstration to evaluate learning. Observing the caregiver perform turning maneuvers, repositioning, managing incontinence, and providing general skin care can be enlightening and provides a context in which the clinician supports and follows up education. In palliative care, it is important to include the reasons for specific actions, such as the continuation of some level of turning and repositioning to prevent further tissue damage and lessen discomfort from additional wounds.

**Summary**

Poorly managed pressure ulcers can increase pain and suffering in those with a chronic debilitating illness. Although preventive measure in patients identified as at risk for developing such pressure ulcers can be effective, some patients do develop pressure ulcers that require expert nursing management. Expert nursing management includes instituting preventive measure to preserve intact skin, obtaining and maintaining a clean wound, management of exudate and odor, and prevention of complications such as a superimposed wound infection. Because many dying and chronically ill debilitated patients are cared for at home, educating family members about the development of pressure ulcers and involving family caregivers in the plan of care is critical.

General Guidelines:

Fill out the attached rating sheet to assess a wound’s status after reading the definitions and methods of assessment described below. Evaluate once a week and whenever a change occurs in the wound. Rate according to each item by picking the response that best describes the wound and entering that score in the item score column for the appropriate date. When you have rated the wound on all items, determine the total score by adding together the 13-item scores. The HIGHER the total score, the more severe the wound status. Plot total score on the Wound Status Continuum to determine progress.

Specific Instructions:
1. **Size:** Use ruler to measure the longest and widest aspect of the wound surface in centimeters; multiply length x width.

2. **Depth:** Pick the depth, thickness, most appropriate to the wound using these additional descriptions:
   - 1 = tissues damaged but no break in skin surface.
   - 2 = superficial, abrasion, blister or shallow crater. Even with, &/or elevated above skin surface (e.g., hyperplasia).
   - 3 = deep crater with or without undermining of adjacent tissue.
   - 4 = visualization of tissue layers not possible due to necrosis.
   - 5 = supporting structures include tendon, joint capsule.

3. **Edges:** Use this guide:
   - Indistinct, diffuse = unable to clearly distinguish wound outline.
   - Attached = even or flush with wound base, no sides or walls present; flat.
   - Not attached = sides or walls are present; floor or base of wound is deeper than edge.
   - Rolled under, thickened = soft to firm and flexible to touch.
   - Hyperkeratosis = callous-like tissue formation around wound & at edges.
   - Fibrotic, scarred = hard, rigid to touch.

4. **Undermining:** Assess by inserting a cotton tipped applicator under the wound edge; advance it as far as it will go without using undue force; raise the tip of the applicator so it may be seen or felt on the surface of the skin; mark the surface with a pen; measure the distance from the mark on the skin to the edge of the wound. Continue process around the wound. Then use a transparent metric measuring guide with concentric circles divided into 4 (25%) pie-shaped quadrants to help determine percent of wound involved.

5. **Necrotic Tissue Type:** Pick the type of necrotic tissue that is predominant in the wound according to color, consistency and adherence using this guide:
   - White/gray non-viable tissue = may appear prior to wound opening; skin surface is white or gray.
   - Non-adherent, yellow slough = thin, mucinous substance; scattered throughout wound bed; easily separated from wound tissue.
   - Loosely adherent, yellow slough = thick, stringy, clumps of debris; attached to wound tissue.
   - Adherent, soft, black eschar = soggy tissue; strongly attached to tissue in center or base of wound.
   - Firmly adherent, hard/black eschar = firm, crusty tissue; strongly attached to wound base and edges (like a hard scab).

6. **Necrotic Tissue Amount:** Use a transparent metric measuring guide with concentric circles divided into 4 (25%) pie-shaped quadrants to help determine percent of wound involved.
7. **Exudate Type:** Some dressings interact with wound drainage to produce a gel or trap liquid. Before assessing exudate type, gently cleanse wound with normal saline or water. Pick the exudate type that is predominant in the wound according to color and consistency, using this guide:

<table>
<thead>
<tr>
<th>Type</th>
<th>Consistency</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bloody</td>
<td>thin, bright red</td>
</tr>
<tr>
<td>Serosanguineous</td>
<td>thin, watery pale red to pink</td>
</tr>
<tr>
<td>Serous</td>
<td>thin, watery, clear</td>
</tr>
<tr>
<td>Purulent</td>
<td>thin or thick, opaque tan to yellow</td>
</tr>
<tr>
<td>Foul purulent</td>
<td>thick, opaque yellow to green with offensive odor</td>
</tr>
</tbody>
</table>

8. **Exudate Amount:** Use a transparent metric measuring guide with concentric circles divided into 4 (25%) pie-shaped quadrants to determine percent of dressing involved with exudate. Use this guide:

<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>None</td>
<td>wound tissues dry.</td>
</tr>
<tr>
<td>Scant</td>
<td>wound tissues moist; no measurable exudate.</td>
</tr>
<tr>
<td>Small</td>
<td>wound tissues wet; moisture evenly distributed in wound; drainage involves ≤ 25% dressing.</td>
</tr>
<tr>
<td>Moderate</td>
<td>wound tissues saturated; drainage may or may not be evenly distributed in wound; drainage involves &gt; 25% to ≤ 75% dressing.</td>
</tr>
<tr>
<td>Large</td>
<td>wound tissues bathed in fluid; drainage freely expressed; may or may not be evenly distributed in wound; drainage involves &gt; 75% of dressing.</td>
</tr>
</tbody>
</table>

9. **Skin Color Surrounding Wound:** Assess tissues within 4 cm of wound edge. Dark-skinned persons show the colors "bright red" and "dark red" as a deepening of normal ethnic skin color or a purple hue. As healing occurs in dark-skinned persons, the new skin is pink and may never darken.

10. **Peripheral Tissue Edema & Induration:** Assess tissues within 4 cm of wound edge. Non-pitting edema appears as skin that is shiny and taut. Identify pitting edema by firmly pressing a finger down into the tissues and waiting for 5 seconds, on release of pressure, tissues fail to resume previous position and an indentation appears. Induration is abnormal firmness of tissues with margins. Assess by gently pinching the tissues. Induration results in an inability to pinch the tissues. Use a transparent metric measuring guide to determine how far edema or induration extends beyond wound.

11. **Granulation Tissue:** Granulation tissue is the growth of small blood vessels and connective tissue to fill in full thickness wounds. Tissue is healthy when bright, beefy red, shiny and granular with a velvety appearance. Poor vascular supply appears as pale pink or blanched to dull, dusky red color.

12. **Epithelialization:** Epithelialization is the process of epidermal resurfacing and appears as pink or red skin. In partial thickness wounds it can occur throughout the wound bed as well as from the wound edges. In full thickness wounds it occurs from the edges only. Use a transparent metric measuring guide with concentric circles divided into 4 (25%) pie-shaped quadrants to help determine percent of wound involved and to measure the distance the epithelial tissue extends into the wound.
Skin Disorders: Tumor Necrosis, Fistulas, and Stomas

This constant drainage smells so bad, and my skin is so sore, life isn’t worth living—I don’t belong among people.—A palliative care patient

Key Points
- Management of drainage and odor are key components of palliative care for malignant cutaneous wounds or tumor necrosis.
- Palliative care for the person with an ostomy is focused on maintenance of an efficient management plan and provision for optimal functional capacity.
- It is essential to involve caregivers and family members in the plan of care.

TUMOR NECROSIS

Definition
Tumor necrosis, also known in the literature as fungating tumors, ulcerative malignant wounds, or malignant cutaneous wounds, presents both a physical and an emotional challenge for the patient and even the most experienced clinician. These wounds are frequently associated with pain, odor, bleeding, and an unsightly appearance. They may be a blow to self-esteem and may cause social isolation just when the patient needs more time with loved ones. The goals in the care of patients with tumor necrosis include pain management; control of exudate, odor, and bleeding; and prevention of infection.

Malignant cutaneous lesions occur in up to 5% of patients with cancer and 10% of patients with metastatic disease. Lookingbill and colleagues’ retrospectively reviewed data accumulated over a 10-year period from the tumor registry at Hershey Medical Center in Pennsylvania. Of 7316 patients, 367 (5.0%) had cutaneous malignancies. Of these, 38 patients had lesions as a result of direct local invasion, 337 had metastatic lesions, and 8 had both. A secondary analysis from the same registry found that 420 patients (10.4%) of 4020 with metastatic disease had cutaneous involvement. In women, the most common origins of metastasis were breast carcinoma (70.7%) and melanoma (12.0%). In men, melanoma (32.3%), lung carcinoma (11.8%), and colorectal cancer (11.0%) accounted for the most common primary tumors. Although these types of cancer account for the majority of skin involvement, it is important to note that metastatic cutaneous lesions may arise from any type of malignant tumor.

Pathophysiology of Tumor Necrosis
Tumor necrosis may occur from infiltration of the skin by local invasion of a primary tumor or by metastasis from a distant
site. Local invasion may initially manifest as inflammation with induration, redness, heat, tenderness, or some combination of these features. The skin may have a peau d’orange appearance and may be fixed to underlying tissue. As the tumor spreads and further tissue destruction occurs, the skin eventually ulcerates. The presentation differs in metastatic cutaneous infiltration. Tumor cells detach from the primary site and travel via blood or lymphatic vessels, or tissue planes, to distant organs, including the skin. These lesions may initially manifest as well-demarcated, painless nodules ranging in size from a few millimeters to several centimeters. Their consistency may vary from firm to rubbery. Pigmentation changes may be noted over the lesions, from deep red to brown-black. Over time, these nodules may ulcerate, drain, and become very painful.

As both locally invasive and metastatic lesions extend, changes in vascular and lymphatic flow lead to edema, exudate, and tissue necrosis. The resulting lesion may be fungating, in which the tumor mass extends above the skin surface with a fungus or cauliflower-like appearance, or it may be erosive and ulcerative. The wound bed may be pale to pink with very friable tissue, completely necrotic, or a combination of both. The surrounding skin may be erythematous, fragile, and exceedingly tender to touch. The skin may also be macerated in the presence of excessive wound exudate. The presence of necrotic tissue is an ideal culture medium for bacterial colonization, which results in significant malodor. The degree of pain experienced by the patient depends on wound location, depth of tissue invasion and damage, nerve involvement, and the patient’s previous experience with pain and analgesia.

**Tumor Necrosis Assessment**

Assessment of tumor necrosis provides the clinician with information to develop a treatment plan, adjust the treatment plan as assessment parameters change, and observe for wound complications. Specifically, wound location, size, appearance, exudate, odor, and condition of the surrounding skin guide local therapy. Associated symptoms should be noted so that appropriate measures can be taken to provide comfort. The potential for serious complications such as hemorrhage, vessel compression or obstruction, or airway obstruction should be noted so that the caregiver can be educated regarding their palliative management. Table 16B-1 presents highlights for the assessment of tumor necrosis and associated symptoms.

Haisfield-Wolfe and Baxendale-Cox proposed a staging classification system for assessment of malignant cutaneous wounds. Use of wound classification may increase the effectiveness of communication among health care practitioners and make evaluation of treatment effectiveness consistent. In a pilot study with 13 wounds, they proposed a staging classification system that evaluates wound depth with clinical descriptors, predominant color of the wound, hydration status of the wound, drainage, pain, odor, and presence of tunneling or undermining. Use of this system provides a basis for a standard set of descriptors that nurses can use to both understand and assess tumor necrosis wounds.

Wounds secondary to tumor necrosis are expected to change over time based on the aggressiveness of the cancer and whether the patient is undergoing palliative surgery, chemotherapy, or radiation. Although palliative treatment may result in regression or even disappearance of the cutaneous lesion, it can be expected to recur eventually. Ongoing assessment allows the clinician to tailor the local wound management based on the current needs of the patient and wound.

**Tumor Necrosis Management**

The goals of care for patients with tumor necrosis include control of infection and odor, management of exudate, prevention and control of bleeding, and management of pain. In determining the appropriate treatment regimen, the abilities of the caregiver must also be considered. The limited information on treatment effectiveness reflects the absence of evidence-based care in this area and the extreme need for further research and dissemination of findings. Many articles are based on expert opinion and the personal experience of practitioners knowledgeable in palliative and hospice care. Although research-based treatment is the gold standard of care, anecdotal reports on successful treatment of these challenging wounds is helpful to nurses striving to provide the best care.

**Infection and Odor Control.** Control of infection and odor is achieved by controlling local bacterial colonization with wound cleansing, wound debridement, and use of local antibiotic agents. Because malignant cutaneous lesions are frequently associated with necrotic tissue and odor, wound cleansing is essential to remove necrotic debris, decrease bacterial counts, and thus reduce odor. If the lesion is not very friable, the patient may be able to get in the shower. This not only provides for local cleansing but also gives the added psychological benefit of helping the patient to feel clean. The patient should be instructed to allow the shower water to hit the skin above the wound and then run over the wound. If there is friable tissue (i.e., tissue that bleeds easily with minimal trauma) or the patient is not able to shower, the nurse or caregiver should gently irrigate the wound with normal saline or a commercial wound cleanser. Skin cleansers, which contain mild soaps and antibacterial ingredients used in bathing, can be very helpful in controlling local colonization and odor. As long as they do not cause burning, they may be sprayed directly on the wound and can be quite effective at controlling odor. If pain and burning occur with use of skin cleansers in the wound, they should be used only on the surrounding skin. Topical antimicrobial agents such as hydrogen peroxide, Dakin’s solution, and povidone iodine are recommended by some authors; however, their use should be weighed against the potential negative effects of local pain, wound desiccation with subsequent pain and bleeding on dressing removal, and unpleasant odor associated with some agents (Dakin’s and povidone iodine), which may be bothersome to patients. In the authors’ experience, the skin cleansers described provide cleansing and odor reduction without many of the negative effects of the topical antimicrobial agents.
Necrotic tissue in tumor necrosis is typically moist yellow slough. Occasionally, in the absence of exudate, there may be dry black eschar, but this is uncommon. Debridement is best done with the use of autolytic and/or gentle mechanical methods, as opposed to wet-to-dry dressings, which are traumatic and can cause significant bleeding on removal. Autolytic debridement can be achieved with the use of dressings that support a moist wound environment, but odor may be increased under occlusion and/or with the use of hydrogels. Local debridement may be performed by very gently scrubbing the necrotic areas with gauze saturated with skin or wound cleanser. Low-pressure irrigation with normal saline using a 35-ml syringe and a 19-gauge needle can be used to remove loose necrotic tissue and decrease bacterial counts. Care should be taken to avoid causing pain with either procedure. In addition, careful sharp debridement by clinicians trained in

</table>
Disadvantages include cost (comparable to metronidazole 0.75% gel) and possible burning on application.

Less conventional methods of odor management are also available. Topical use of yogurt or buttermilk has been reported to be successful at eliminating some tumor necrosis odors. The yogurt or buttermilk is applied topically to the wound after cleansing. These substances may work by decreasing the wound pH, thus stunting bacterial proliferation and the resultant odor. It is theorized that the low pH of the lactobacilli present in the yogurt or buttermilk is responsible for the alteration in wound pH. There are limited studies supporting the use of yogurt or buttermilk, and none has addressed specific limitations or contraindications for use. Use of peppermint oil or other aromatherapy products, as well as cat litter, in the environment around the patient may also help to eliminate wound odor.

Use of charcoal dressings, which absorb and trap odor, may also be helpful in odor management. Charcoal dressings may be used as either primary or secondary dressings. Because these dressings vary in their application and performance, package inserts should be reviewed before use. A basket of charcoal under the bed or table may also help to rid the environment of wound odor in the home setting.

Although local colonization is treated with topical cleansing, debridement, and antibacterial agents, clinical infection (as evidenced by erythema, induration, increased pain and exudate, leukocytosis, and fever) should be treated with systemic antibiotics. Cultures should be used to identify infecting organisms once the wound is diagnosed with an infection based on clinical signs; cultures should not be used routinely to diagnose infection. Because of the local inflammatory effects of the tumor, wounds may have many of the same signs as infection, so the clinician must be discriminating in differentiating between the two. A complete blood count, assessing the white cell count and differential, may be helpful in guiding assessment and therapy. It is crucial to avoid treating patients with oral antibiotics if they are only colonized and not infected, to prevent side effects and emergence of resistant organisms.

**Management of Exudate.** Because of the inflammation and edema commonly associated with these wounds, there tends to be significant exudate. Dressings should be chosen to conceal and collect exudate and odor. It is essential to use dressings that contain the exudate, because a patient who experiences unexpected drainage on clothing or bedding may suffer significant feelings of distress and loss of control. Specialty dressings, such as foams, alginates, or starch copolymers, are notably more expensive than gauze pads or cotton-based absorbent pads. However, if such dressings reduce the overall cost by reducing the need for frequent dressing changes, they may be cost-effective. Table 16B–2 summarizes tumor necrosis dressing considerations. Nonadherent dressings are best for the primary contact layer, because they minimize the trauma to the wound associated with dressing changes.

Seaman suggested using nonadherent contact layers, such as Vaseline gauze, for the primary dressing on the wound bed,
and covering these with soft, absorbent dressings, such as gauze and ABD pads, for secondary dressings to contain drainage. The entire dressing is changed once a day; the secondary dressing should be changed twice a day if drainage strikes through to the outside of the bandage. Menstrual pads may be advantageous, not only because of their excellent absorption but also because the plastic backing blocks exudate and protects clothing. Protection of the surrounding skin is another goal of exudate management.

The skin around the tumor necrosis may be fragile secondary to previous radiation therapy, inflammation due to tumor extension, repeated use of adhesive dressings, or maceration. Although adhesive dressings may assist with drainage and odor control, their potential to strip the epidermis on removal may outweigh their benefit. Using ostomy skin barriers on the skin surrounding the wound and then taping the dressings to the skin barriers (changing them every 5 to 7 days) is one method of protecting surrounding skin from excess drainage and also from the skin stripping that results with dressing changes when tape is used. Another method of protecting the surrounding skin is to use a barrier ointment or skin sealant on the skin surrounding the ulcer. These barriers protect the fragile tissue from maceration and the irritating effects of the drainage on the skin. Dressings can then be held in place with Montgomery straps or tape affixed to a skin barrier placed on healthy skin, flexible netting, tube dressings, sports bras, panties, and the like.

**Controlling Bleeding.** The viable tissue in a malignant lesion may be very friable, bleeding with even minimal manipulation. Prevention is the best therapy for controlling bleeding. Prevention involves use of a gentle hand in dressing removal and thoughtful attention to the use of nonadherent dressings or moist wound dressings. On wounds with a low amount of exudate, the use of hydrogel sheets, or amorphous hydrogels under a nonadherent contact layer, may keep the wound moist and prevent dressing adherence. Even highly exudating wounds may require a nonadherent contact layer to allow for atraumatic dressing removal. If dressings adhere to the wound on attempted removal, they should be soaked away with normal saline to lessen the trauma to the wound bed. If bleeding does

Several types of pain are associated with tumor necrosis. Clinicians should not hesitate to consider these options if they will improve the quality of life in patients with tumor necrosis. All three were receiving systemic opioid therapy. The patients on a daily basis. Two of the patients had painful pressure ulcers, and the third had a painful malignant ulceration. Nurses should discuss this option for topical pain relief with individual patients and physicians. Because wound care is performed frequently in these patients, topical opioids may be an excellent adjunct to the pain management plan.

**Patient and Caregiver Education**

The same education provided to patients and caregivers about basic wound care should be provided to those dealing with tumor necrosis. Frequency and procedures for dressing changes, including time of premedication for pain management and alternatives for odor control, should be presented and reinforced. Patient and caregiver education must also focus on the psychosocial aspects of tumor necrosis. Patients are often unable to separate themselves from the wound and may feel as if their bodies are rotting away. Indeed, patients are often unable to view the wound, may become nauseous or retch when dressing changes are performed, or may exhibit other signs of low self-esteem related to the wound. The nurse can facilitate a trusting relationship with the patient by reviewing the goals of care and by openly discussing issues that the patient may not have talked about with other providers. For example, it is helpful to acknowledge odor openly and then discuss how it will be managed. Attention to the cosmetic appearance of the wound with the dressing in place can assist the patient in dealing with body image disturbances. Use of flexible dressings (e.g., foam dressings) and dressings that can fill a defect (e.g., calcium alginate, soft nonwoven gauze) may be appropriate to restore symmetry and provide adequate cosmesis for the patient.

Isolation may result from embarrassment, shame, or guilt. Caregivers may be overcome by the appearance of the wound or the other associated characteristics, such as odor. Assisting the patient and the caregiver to deal with the distressing symptoms of the tumor necrosis so that odor is managed, pain is alleviated, and exudate contained improves the quality of life for these patients and contributes to the goal of satisfactory psychological well-being. Education must include realistic goals for the wound. In cases of tumor necrosis, the goal of complete wound healing is seldom achievable, but through attention to exudate, odor, and pain, quality of life can be maintained even as the tumor necrosis wound degenerates. Determination of priority goals in palliation may be the first step in patient and caregiver education. For example, if the patient is most disturbed by odor, measures to address wound odor should be foremost in the treatment plan. Continual education and evaluation of the effectiveness of the treatment plan are essential to maintaining quality of life for those with tumor necrosis.

### FISTULAS

**Definition**

A fistula is an abnormal passage or opening between two or more body organs or spaces. The most frequently involved organs are the skin and either the bladder or the digestive tract, although fistulas can occur between many other body organs.
and/or spaces. Often, the organs involved and the location of the fistula influence management methods and complicate care. For example, fistulas involving the small bowel and the vaginal vault and those involving the esophagus and skin create extreme challenges in care related to both the location and the organs involved in the fistula. Although spontaneous closure occurs in at least 50% of all enteric or small-bowel fistulas, the time required to achieve closure is 4 to 7 weeks, so long-term treatment plans are required for all patients with fistulas. Ninety percent of those fistulas that close spontaneously do so within the 4- to 7-week time frame. Therefore, if the fistula has not spontaneously closed with adequate medical treatment within 7 weeks, the goal of care may change to palliation, particularly if chances of closure are limited by other factors. Factors that inhibit fistula closure include complete disruption of bowel continuity, distal obstruction, presence of a foreign body in the fistula tract, an epithelium-lined tract contiguous with the skin, presence of cancer, previous radiation, and Crohn’s disease. The presence of any of these factors can be deleterious for spontaneous closure of a fistula. The goals of management for fistula care involve containment of effluent, management of odor, comfort, and protection of the surrounding skin and tissues.

**Pathophysiology of Fistula Development**

In cancer care, those with gastrointestinal cancers and those who have received irradiation to pelvic organs are at highest risk for fistula development. Fistula development occurs in 1% of patients with advanced malignancy. In most cases of advanced malignancy, the fistula develops in relation to either obstruction from the malignancy or irradiation side effects. Radiation therapy damages the vasculature and underlying structures. In cancer-related fistula development, management is almost always palliative. However, fistula development is not limited to patients with cancer.

In addition to cancer and radiation therapy, postsurgical adhesions, inflammatory bowel disease (Crohn’s disease), and small-bowel obstruction place an individual at high risk for fistula development. The number one cause of fistula development is postsurgical adhesions. Adhesions are scar tissues that cause fistula development by providing an obstructive process within the normal passageway. Those with inflammatory bowel disease, Crohn’s disease in particular, are prone to fistula development by virtue of the effects of the disease process on the bowel itself. Crohn’s disease often involves the perianal area, with fissures and fistulas being common findings. Because Crohn’s disease is a transmural disease, involving all layers of the bowel wall, patients are prone to fistula development. Crohn’s disease can occur anywhere along the entire gastrointestinal tract, and there is no known cure. Initially, the disease is managed medically with steroids, immunotherapy, and metronidazole for perianal disease. If medical management fails, the patient may be treated with surgical creation of a colostomy, to remove the portion of bowel affected by the disease. In later stages of disease, if medical and surgical management have failed, multiple fistulas may present clinically, and the goal for care becomes living with the fistulas and palliation of symptoms.

Other factors contributing to fistula development include the presence of a foreign body next to a suture line, tension on a suture line, improper suturing technique, distal obstruction, hematoma/abscess formation, tumor or additional disease in anastomotic sites, and inadequate blood supply. Each of these can contribute to fistula formation by promoting an abnormal passage between two body organs. Typically, the contributing factor provides a tract for easier evacuation of stool or urine along the tract rather than through the normal route. Such is the case with a foreign body next to the suture line and with hematoma or abscess formation. In some cases, the normal passageway is blocked, as with tumor growth or obstructive processes. Finally, in many cases, the pathology relates to inadequate tissue perfusion, as with tension on the suture line, improper suturing, and inadequate blood supply.

**Fistula Assessment**

Assessment of the fistula involves assessment of the source, surrounding skin, output, and fluid and electrolyte status. Evaluation of the fistula source may involve diagnostic tests such as radiographs to determine the exact structures involved in the fistula tract. Assessment of the fistula source involves evaluation of fistula output, or effluent, for odor, color, consistency, pH, and amount. These characteristics provide clues to the origin of the output. Fistulas with highly odorous output are likely to originate in the colon or may be related to cancerous lesions. Fistula output with less odor may have a small-bowel origin. The color of fistula output also provides clues to the source: clear or white output is typical of esophageal fistulas, green output is usual of fistulas originating from the gastric area, and light brown or tan output may indicate small-bowel sources. Small-bowel output is typically thin and watery to thick and pasty in consistency, whereas colonic fistulas have output with a pasty to a soft consistency. The volume of output is often an indication of the source. For small-bowel fistulas, output is typically high, with volumes ranging from 500 to 3000 mL over 24 hours, for low-output and high-output fistulas, respectively. Esophageal fistula output may be as high as 1000 mL over 24 hours. Fistulas can be classified according to output, with those producing less than 500 mL over 24 hours classified as low output and those producing greater volumes classified as high output.

The anatomical orifice location, proximity of the orifice to bony prominences, the regularity and stability of the surrounding skin, the number of fistula openings, and the level at which the fistula orifice exits onto the skin influence treatment options. Fistulas may be classified according to the organs involved and the location of the opening of the fistula orifice. Fistulas with openings from one internal body organ to another (e.g., from small bowel to bladder, from bladder to vagina) are internal fistulas; those with cutaneous involvement (e.g., small bowel to skin) are external fistulas.

The location of the fistula often impedes containment of output. Skin integrity should be assessed for erythema,
ulceration, maceration, or denudation from fistula output. Typically, the more caustic the fistula output, the more impaired the surrounding skin integrity. Multiple fistula tracts may also impede containment efforts.

Assessment of fluid and electrolyte balance is essential because of the risk of imbalance in both. In particular, the patient with a small-bowel fistula is at high risk for fluid volume deficit or dehydration and metabolic acidosis due to the loss of large volumes of alkaline small-bowel contents. Significant losses of sodium and potassium are common with small-bowel fistulas. Laboratory values should be monitored frequently. Evaluation for signs of fluid volume deficit is also recommended.

**Fistula Management**

Wherever anatomically possible, the fistula should be managed with an ostomy pouching technique. The surrounding skin should be cleansed with warm water without soap or antiseptics; skin barrier paste should then be used to fill uneven skin surfaces, so that a flat surface is created to apply the pouch. Pediatric pouches are often smaller and more flexible and may be useful for hard-to-pouch areas where flexibility is needed, such as the neck for esophageal fistulas. The type of pouch should be chosen based on the output of the fistula. For example, if the fistula output is watery and thin, a pouch with a narrow spigot or tube for closure is chosen; in contrast, a fistula with a thick, pasty output would be better managed with a pouch with an open end and a closure clamp. Pouches must be emptied frequently, at least when one-third to one-half full. There are several wound drainage pouching systems on the market that allow for visualization and direct access to the fistula through a valve or door that can be opened and closed. These wound management pouches are available in large sizes and often work well for abdominal fistulas. Punching of the fistula allows for odor control (many fistulas are quite malodorous), containment of output, and protection of the surrounding skin from damage. Gauze dressings with or without charcoal filters may be used if the output from the fistula is less than 250 mL over 24 hours and is not severely offensive in odor. Colostomy caps (small closed-end pouches) can be useful for low-output fistulas that continue to be odorous.

There are specific pouching techniques that are useful in complex fistula management, including troughing, saddlebagging, and bridging. These techniques are particularly helpful when dealing with fistulas that occur in wounds, most commonly the small-bowel fistula that develops in the open abdominal wound. Troughing is useful for fistulas that occur in the posterior aspect of large abdominal wounds. The skin surrounding the wound and fistula should be lined with a skin barrier wafer and the edge nearest the wound sealed with skin barrier paste. Then, thin film dressings are applied over the top or anterior aspect of the wound, down to the fistula orifice and the posterior aspect of the wound. Finally, a cut-to-fit ostomy pouch is used to pouch the opening in the thin film dressing at the fistula orifice. Wound exudate drains from the anterior portion of the wound (under the thin film dressing) to the posterior portion of the wound and out into the ostomy pouch, along with fistula output. The trough technique does not prevent fistula output from contaminating the wound site.

The bridging technique prevents fistula output from contaminating the wound site and allows for a unique wound dressing to be applied to the wound site. Bridging is appropriate for fistulas that occur in the posterior aspect of large abdominal wounds, where it is important to contain fistula output away from the wound site. Using small pieces of skin barrier wafers, the clinician builds a “bridge” by consecutively layering the skin barriers together until the skin barrier has the appearance of a wedge or bridge and is the same height as the depth of the wound. With the use of a skin barrier paste, the skin barrier wedge is adhered to the wound bed (it does not harm the healthy tissues of the wound bed), next to the fistula opening. An ostomy pouch is then cut to fit the fistula opening, using the wedge or bridge as a portion of intact surrounding skin to adhere the pouch. The anterior aspect of the wound may then be dressed with the dressing of choice.

Saddlebagging is used for multiple fistulas, if it is important to keep the output from each fistula separated and the fistula orifices are close together. Two cut-to-fit ostomy pouches (or more for more fistulas) are used. The fistula openings are cut on the back of the pouch, off-center or as far to the side as possible, and the second pouch is cut to fit the next fistula, off-center as far to the other side as possible. The skin is cleansed with warm water, and skin barrier paste is applied around the orifices. Ostomy pouches are applied, and, where they contact each other (down the middle), they are affixed or adhered to each other in a “saddlebag” fashion. Multiple fistulas can also be managed with one ostomy pouching system that accommodates the multiple openings. Consultation with an enterostomal therapy (ET) nurse or ostomy nurse is extremely advantageous in these cases.

Another method of managing fistulas is by a closed suction wound drainage system. Jeter and colleagues described the use of a Jackson-Pratt drain and continuous low suction in fistula management. After the wound is cleansed with normal saline, the fenestrated Jackson-Pratt drain is placed in the wound, on top of a moistened gauze that has been opened up to line the wound bed (primary contact layer); a second fluffed wet gauze is placed over the drain, and the surrounding skin is prepared with a skin sealant. Next, the entire site is covered with a thin film dressing, which is crimped around the tube of the drain where it exits the wound. The tube exit site is filled with skin barrier paste, and the drain is connected to low continuous wall suction; the connection site may need to be adjusted and may require use of a small “Christmas tree” connector or device and tape to secure it. Jeter and colleagues advised changing the system every 3 to 5 days. Others have used a similar setup for pharyngocutaneous fistulas. A wound closure device that provides intermittent or continuous subatmospheric pressure offers additional options for fistula management.

Pouches to contain the fistula output usually involve odor as well. If odor continues to be problematic with an intact
pouching system, internal body deodorants such as bismuth subgallate, charcoal compositions, or peppermint oil may be helpful.\textsuperscript{37} Taking care to change the pouch in a well-ventilated room also helps with odor. If odor is caused by anaerobic bacteria, use of 400 mg metronidazole orally three times a day may be helpful. Management of high-output fistulas may be improved with administration of octreotide 300 mcg subcutaneously over 24 hours.\textsuperscript{33}

Nutrition management and fluid and electrolyte maintenance are essential for adequate fistula care. Fluid and nutritional requirements may be greatly increased with fistulas, and there are difficulties with fistulas that involve the gastrointestinal system. As a general guideline, the intestinal system should be used whenever possible for nutritional support. If nutrition can bypass the fistula site, absorption and tolerance are better with use of the intestinal tract. For small-bowel fistulas, bypass of the fistula orifice is not always feasible. If the small-bowel fistula is located distally, enough of the intestinal tract may be available to adequately absorb nutrients before the fistula orifice is reached. If the fistula is located more proximally, there may not be enough intestinal tract available for nutrient absorption ahead of the fistula orifice. Many of these patients must be given intravenous hyperalimentation during the early stages of fistula management. The specific goals of fluid and electrolyte and nutritional support for fistula management must be discussed with the patient and family in view of the palliative nature of the overall care plan.

Patient and Caregiver Education

Patient and caregiver teaching first involves adequate assessment of the self-care ability of the patient and of the caregiver’s abilities. The patient and caregiver must be taught the management method for the fistula, including pouching techniques, how to empty the pouch, odor control methods, and strategies for increasing fluid and nutritional intake. Many of the pouching techniques used to manage fistulas are complicated and may require continual surveillance by an expert such as an ET nurse or ostomy nurse.

PALLIATIVE STOMA CARE

The significance of palliative care for an individual with a stoma is to improve well-being during this critical time and to attain the best quality of life possible. In regard to the stoma, palliative care is achieved by restoring the most efficient management plan and providing optimal functional capacity. It is essential to involve the family in the plan of care and to provide care to the extent of the patient’s wishes.

Management of the ostomy includes physical care as well as psychological and social care. To meet the needs of the patient and family, access to the multidisciplinary care team is crucial. This team may include the ET nurse, physicians such as the surgeon and oncologist, a nutritionist, and social service personnel.

The urinary or fecal stoma can be managed (by the ET nurse) to incorporate the needs and goals of both the patient and the caregiver and to provide the highest quality of life possible.

Pathophysiology

A stoma is an artificial opening in the abdominal wall that is surgically created to allow urine or stool to be eliminated by an alternative route. The most common indications for the creation of a stoma are as follows:

1. Cancers that interfere with the normal function of the urinary or gastrointestinal system
2. Inflammatory bowel diseases such as Crohn’s or ulcerative colitis
3. Congenital diseases such as Hirschsprung’s disease or familial adenomatous polyposis
4. Trauma

In planning the care of an individual with a stoma, it is necessary to understand the type of ostomy that was created, including the contents that will be eliminated.

Types of Diversion

The three types of diversion created with a stoma as the outlet for urine or stool are the ileoconduit (urinary output), the ileostomy (fecal output), and the colostomy (fecal output). Construction of any of these diversions requires the person to wear an external appliance to collect the output.

Ileoconduit. Since the early 1950s, the Bricker ileoconduit has been the primary method for diverting urinary flow in the absence of bladder function. This procedure involves isolation of a section of the terminal ileum. The proximal end is closed, and the distal end is brought out through an opening in the abdominal wall at a site selected before surgery. The ileal segment is sutured to the skin, creating a stoma. The ureters are implanted into the ileal segment, urine flows into the conduit, and peristalsis propels the urine out through the stoma. An external appliance is worn to collect the urine; it is emptied when the pouch is one-third to one-half full, or approximately every 4 hours.

Ileostomy. The ileostomy is created to divert stool away from the large intestine, typically using the terminal ileum. The stoma is created by bringing the distal end of the ileum through an opening surgically created in the abdominal wall and suturing it to the skin. The output is usually a soft, unformed to semifomed stool. Approximately 600 to 800 mL/day is eliminated. An external appliance is worn to collect the fecal material; it is emptied when the bag is one-third to one-half full, usually four to six times per day.

An ileostomy may be temporary or permanent. A temporary ileostomy usually is created when the colon needs time to heal or rest, such as after colon surgery or a colon obstruction. A permanent ileostomy is necessary if the entire colon, rectum,
and anus has been surgically removed, such as in colorectal cancer or Crohn’s disease.

**Colostomy.** The colostomy is created proximal to the affected segment of the colon or rectum. A colostomy may be temporary or permanent. There are three sections of the colon: the ascending, transverse, and descending colon. The section of colon used to create the stoma determines in part the location and the consistency of output, which may affect the nutritional and hydration status of the individual at critical times. The ascending colon stoma usually is created on the right midquadrant of the abdomen, and the output is a semifomed stool. The transverse stoma is created in the upper quadrants and is the largest stoma created; the output is usually a semi-formed to formed stool. The descending colon stoma most closely mirrors the activity of normal bowel function; it usually is located in the lower left quadrant.

The stoma is created by bringing the distal end of the colon through an opening surgically created in the abdominal wall and suturing it to the skin. An external appliance is worn to collect the fecal material; it is emptied when the bag is one-third to one-half full, usually one or two times per day. A second option for management is irrigation, to regulate the bowel. The patient is taught to instill 600 to 1000 mL of lukewarm tap water through the stoma, using a cone-shaped irrigation apparatus. This creates bowel distention, stimulating peristaltic activity and therefore elimination within 30 to 45 minutes. Repetition of this process over time induces bowel dependence on the stimulus, reducing the spillage of stool between irrigations. The elimination process after initial evacuation is suppressed for 24 to 48 hours.

**Assessment**

**Stoma Characteristics.** Viability of the stoma is assessed by its color. This should be checked regularly, especially in the early postoperative period. Normal color of the stoma is deep pink to deep red. The intestinal stomal tissue can be compared with the mucosal lining of the mouth. The stoma may bleed when the muscle defect created at the time of stoma formation and is the largest stoma created; the output is usually a semifomed to formed stool. The descending colon stoma most closely mirrors the activity of normal bowel function; it usually is located in the lower left quadrant.

Repetition of this process over time induces bowel dependence on the stimulus, reducing the spillage of stool between irrigations. The elimination process after initial evacuation is suppressed for 24 to 48 hours.
Stenosis of the stoma can occur at the skin level or at the level of the fascia. Stenosis that interferes with normal bowel elimination requires intervention. Signs and symptoms of stenosis include change in bowel habits (e.g., decreased output, thin-caliber stools), abdominal cramping, abdominal distention, flank pain from urinary stomas, and nausea or vomiting. The stenotic area may be managed conservatively by dilatation or may require surgical intervention by local excision or laparotomy. Stenosis that interferes with normal bowel outflow of urine or stool from the stoma requires the individual to wear an external appliance at all times. Ideally, the stoma protrudes one-half to three-fourths of an inch above the skin surface, to allow the urine or stool to drain efficiently into a pouch. The objective of stoma management is to protect the peristomal skin, contain output, and control odor.

Peristomal Skin Problems. Peristomal skin complications commonly include mechanical breakdown, chemical breakdown, rash, and allergic reaction. Mechanical breakdown is caused by trauma to the epidermal skin layer. This is most often related to frequent appliance changes that cause shearing or tearing to the epidermal skin. The result is denuded skin or erythematous, raw, moist, and painful skin. The use of pectin-based powder with or without a light coating of skin sealant aids in healing and protecting the skin from further damage while allowing appliance adherence.

Chemical breakdown is caused by prolonged contact of urine or fecal effluent with the peristomal skin. Inappropriate use of adhesive skin solvents may also result in skin breakdown. The result of chemical breakdown is denudation of the peristomal skin that has been exposed to the caustic effects of the stool, urine, or adhesive solvents. Prompt recognition and management are essential. Modification of the pouching system, such as using a convex wafer instead of a flat wafer or adding protective skin products such as a paste (or both) can be used to correct the underlying problem. Instructing patients and caregivers to thoroughly cleanse the skin with plain water after using the skin solvent can eliminate the problem of denuded skin. Treatment of denuded skin is the same as described previously.

A peristomal fungal rash can occur as a result of excessive moisture or antibiotic administration that results in overgrowth of yeast in the bowel or, at the skin level, due to perspiration under a pouch or leakage of urine or stool under the barrier. The rash is characterized as having a macular, red border with a moist, red to yellow center; it is usually pruritic. Application of antifungal powder, such as nystatin powder, to the affected areas usually produces a prompt response. Blotting the powder with skin preparation or sealant may allow the pouching system to adhere more effectively.

Allergic reactions are most often caused by the barrier and tape used for the pouching system. Erythematous vesicles and pruritus characterize the area involved. Management includes removal of the offending agent. The distribution of the reaction can usually aid in defining the allergen. It may be necessary to perform skin testing if the causative agent is not clear. Patients with sensitive skin and those who use multiple products may respond to simple pouching techniques such as using water to clean the skin, patting the skin dry, and applying the wafer and pouch without the use of skin preparations. Changing to products from a different manufacturer may also eliminate the allergen. A nonadhesive pouching system may be used temporarily for patients with severe blistering and hypersensitivity, to allow healing and prevent further peristomal skin damage. Patients with severe blistering and pruritus may also require temporary use of systemic or topical antihistamines or corticosteroids.

Principles and Products for Pouching a Stoma. The continuous outflow of urine or stool from the stoma requires the individual to wear an external appliance at all times. Ideally, the stoma protrudes one-half to three-fourths of an inch above the skin surface, to allow the urine or stool to drain efficiently into a pouch. The objective of stoma management is to protect the peristomal skin, contain output, and control odor.

The skin around the stoma should be cleaned and thoroughly dried before the appliance is positioned over the stoma. An effective pouch should adhere for at least 3 days, although this is not always possible. If no leakage occurs, the same pouch may remain adhered to the skin for up to 10 days. It should then be changed for hygienic reasons and to observe the peristomal area. Today, there is an ever-changing supply of new appliances. Materials and design are being updated rapidly to provide the consumer with the best protection and easiest care. Factors to consider when choosing a pouch include the consistency and type of effluent, the contour of the abdomen, the size and shape of the stoma, and the extent of protrusion, as well as patient preferences.

Pouching systems are available as one-piece or two-piece systems. The one-piece system is constructed with the odor-proof pouch joined to a barrier ring that adheres to the skin. The barrier can be precut to the size of the stoma, or it can be customized with a cut-to-fit barrier. A two-piece system usually consists of an individual barrier with a flange ring and an odor-proof pouch, which attach (snap) together by matching the ring size of the barrier and pouch. The pouch barrier may be flat or convex and is chosen based on the contour of the abdomen and the extent of stoma protrusion. The colostomy pouch may be closed-ended or open-ended with a clip for closure. Some individuals choose to clean the pouch daily. The pouch of the one-piece system can be cleaned by instilling water into the pouch (with a syringe or turkey baster) and rinsing while preventing the water from reaching the stoma area. The pouch of the two-piece system can be cleaned daily by detaching and washing it in the sink with soap and water and drying it before reattaching it to the barrier.

The urinary pouch has a spout opening to allow for controlled emptying of the pouch. This end may also be attached to a bedside bag or bottle to collect urine. It typically holds up to 2000 mL of urine. The urinary system can be easily disassembled and cleaned with soap and water. After cleaning, a vinegar-and-water solution should be rinsed through the tubing and bag/bottle to prevent urine crystallization.

Skin barriers, skin sealants, powders such as Stomahesive powder or karaya powder, and pastes such as Stomahesive paste...
or karaya paste are available to protect the peristomal skin from the caustic affects of urine or stool. These products may also be used to aid in the healing of peristomal skin problems.

Belts and binders are available to assist in maintaining pouch adherence and for management of certain stoma problems. Table 16B–3 presents an overview of pouching options for patients with fecal or urinary diversions.

Interventions

Prevention of Complications. Stoma surgery performed as a palliative measure is not intended to provide a cure but rather to alleviate difficulties such as obstruction, pain, or severe incontinence. Unfortunately, at a difficult time in patients’ and families’ lives, the created stoma disrupts normal physical appearance, normal elimination of urine or stool, and control of elimination with in some cases loss of body parts and/or sexual function. The patient then has to learn to care for the stoma or allow someone else to care for them. Physically and psychologically, the patient has to come to terms with the presence of the stoma, its function, and care. This takes time and energy to cope emotionally, physically, and socially.38

Educating the patient and family regarding management issues related to ostomy care and palliation could assist in the physical and psychological adaptation to the ostomy. Additional therapies that may be required for treatment of the underlying disease or a new disease process, such as progressed or recurrent cancer, may affect the activity of the stoma or the peristomal skin. Additional therapies may include chemotherapy, radiation therapy, or analgesics for pain management.

Chemotherapy and radiation therapy may affect a fecal stoma by causing diarrhea. Associated symptoms include abdominal discomfort, larger quantities of loose or liquid stool produced per day, and potential dehydration and loss of appetite with prolonged diarrhea. The ostomy bag requires more frequent emptying, and the ostomy pouch seal needs to be monitored more closely for leakage. In addition, radiation therapy that includes the stoma in the radiation field can cause peristomal skin irritation, particularly redness and maceration. The effects on the peristomal skin may be exacerbated by leakage of urine or stool, as described earlier.39

Analgesic use may result in constipation and ultimately bowel obstruction. It is necessary to coadminister stool softeners or laxatives for the prevention of constipation. Irrigation of the colostomy may also assist in treating constipation. The patient and family need to be instructed regarding these measures so that they can be used to treat and prevent constipation. The patient and family need to be aware that adequate pain relief and prevention of constipation can be achieved.38,39

Patients may become very tired or may experience anxiety, nausea, or pain as a result of their condition and palliative management. Patients often want to remain as independent as possible but may allow assistance from family and staff. For example, the patient may want to perform the actual pouch change but allow someone else to gather and prepare the supplies. This allows for conservation of energy during part of the task to be accomplished. The patient may also choose the time of day to perform such tasks—when he or she has the most energy and maximal pain and nausea control.42

Nutrition and Hydration. Anorexia and dehydration can be major problems for the patient with advancing disease or disease-related treatments such as chemotherapy and radiation therapy. Compromised ingestion, digestion, and absorption can have major influences on nutritional and hydration status.

Anorexia is the loss of appetite resulting from changes in gastrointestinal function, including changes in taste, changes in metabolism, psychological behaviors, and the effects of disease and treatment. Decreased oral intake and changes in metabolism, including decreased protein and fat metabolism, increased energy expenditure, and increased carbohydrate consumption, result in loss of muscle mass, loss of fat stores, and fatigue, leading to weight loss and malnutrition.43

Managing the underlying cause of poor nutritional and hydration status, such as controlling the cancer or disease, treating an infection, or slowing down the high-volume ileostomy output, can improve the nutritional state. However, despite effective treatment, other assistance may be necessary, such as small and more frequent meals, nutritional liquid supplements, appetite stimulants (e.g., megestrol acetate), corticosteroids, and parenteral or enteral support.44 Foods and drinks need to be appealing to the patient. Strong odors and large-portion meals may result in appetite suppression. Promoting comfort before meals may also increase appetite; this may include administering antiemetics or analgesics, oral care, or resting for 30 minutes before mealtime.43

Management Issues

Controlling odor, reducing gas, and preventing or managing diarrhea or constipation are management issues related to patients with a colostomy. Odor can be controlled by ensuring that the pouch seal is tight, that odor-proof pouches are used, and that a clean pouch opening is maintained. In addition, deodorants such as bismuth subgallate or chlorophyllin copper complex may be taken orally. Gas can be reduced by decreasing
intake of gas-producing foods such as broccoli, cabbage, beans, and beer. Peppermint or chamomile tea may be effective in gas reduction.38,39

Diarrhea can be managed as in a patient with an intact rectum and anus. Diarrhea may be a result of viral illness or use of a chemotherapeutic agent. Management includes increased fluid intake, a low-fiber and low-fat diet, and administration of antidiarrhea medications such as loperamide (Imodium), bismuth subsalicylate (Pepto-Bismol), or diphenoxylate plus atropine (Lomotil) by prescription.40,45 If the patient irrigates, it is necessary to hold irrigation until formed stools return. Constipation more commonly occurs in patients with advanced malignancies due to the effects of analgesic use, reduced activity level, and reduced dietary fiber intake. Management of constipation includes administration of laxatives such as milk of magnesia, mineral oil, or lactulose and initiation of a plan for prevention of constipation with use of stool softeners and laxatives as needed. Cleansing irrigation may be necessary for patients who normally do not irrigate. Cleansing irrigation is performed as described previously for individuals with a colostomy who irrigate for control of bowel movements.40

Skin protection, fluid and electrolyte maintenance, prevention of blockage, and modification of medications are management issues related to an ileostomy. Because of the high-volume liquid or loose stools, protecting the skin from this effluent is critical. Leakage of effluent can cause chemical skin breakdown and pain from the irritated skin. The ET nurse can work with the patient and family to determine the cause of the effluent leak. It may be necessary to modify the pouching system, to ensure a proper fit. The peristomal skin may need to be treated with a powder or skin sealant, or both, to aid in healing. The transit time of food and wastes through the gastrointestinal system and out through the ileostomy is rapid and potentially contributes to dehydration and fluid and electrolyte imbalance. Ensuring adequate fluid and electrolyte intake is essential and may be accomplished by ingestion of sports drinks or nutrition shakes. Patients with an ileostomy are instructed to include fiber in their diet, to bulk stools and promote absorption of nutrition and medications.

Food blockage occurs when undigested food particles or medications partially or completely obstruct the stoma outlet at the fascia level. It is necessary to instruct the patient and family about the signs of a blockage, including malodorous, high-volume liquid output or no output accompanied by abdominal cramping, distention, and/or nausea and vomiting. These symptoms should be reported as soon as they occur. Blockage is resolved by lavage or mini-irrigation performed by the physician or ET nurse. A catheter is gently inserted into the stoma until the blockage is reached, 30 to 60 mL of normal saline is instilled, and the catheter is removed to allow for the return. This process is repeated until the blockage has resolved. Patient teaching should be reinforced regarding the need to chew food well before swallowing, to prevent food blockage. Time-release tablets and enteric-coated medications should be avoided because of inadequate or unpredictable absorption. Medications often come in various forms, including liquid, noncoated, patch, rectal suppository, subcutaneous or intravenous administration. Choosing the most appropriate route that provides the greatest efficacy for the individual is essential. For example, a transdermal patch may be used for analgesia instead of a time-released pain tablet. For patients who have an intact rectum that is no longer in continuity with the proximal bowel, rectal administration of medications is effective.45

Management issues for an individual with an ileoconduit include prevention of a urinary tract infection, stone formation, peristomal skin protection, and odor control. Each of these issues is preventable by the maintenance of dilute and acidic urine through adequate fluid intake (1800 to 2400 mL/day). Vitamin C (500 to 1000 mg/day) and citrus fruits and drinks may assist in accomplishing acidic urine. Alkaline urine can cause encrustations on the stoma and peristomal skin damage with prolonged exposure. Acetic acid soaks may be applied three or four times per day to treat the encrustations until they dissolve. Adjustments in the pouching system may be necessary to prevent leakage of urine onto the skin, and the temporary addition of powder, paste, skin sealant, or some combination of these products may be needed to aid healing of the affected skin.40

**CASE REPORT**

**Mrs. P, a Patient with Bladder Cancer**

Mrs. P is a 75-year-old woman with bladder cancer. She was diagnosed 2 months ago. She presented with symptoms of difficulty passing urine, hematuria, and painful urination. She had a 15-pound weight loss, significant fatigue, and anorexia. Investigations demonstrated a large mass within the bladder with ureteral obstruction, intraabdominal mass, and liver lesions. Mrs. P’s care was complicated by underlying medical conditions including sick sinus syndrome, chronic hyperkalemia, nutritional depletion, and fatigue. Her past medical history included treatment for ovarian cancer 38 years earlier with radiation therapy. She met with the urological surgeon, medical oncologist, and radiation oncologist. The plan of care was determined to be palliative care, with the goal to keep her as comfortable as possible and provide the best quality of life. Her son became her primary caregiver, with assistance from a daughter who lives out of town.

Mrs. P underwent placement of an ileoconduit and began chemotherapy. Radiation therapy was not an option because she had already received maximum radiation exposure. She required placement of a pacemaker at the initiation of chemotherapy. She developed a hypersensitivity reaction, erythema without desquamation, on her abdomen at the site of a prior radiation reaction. This resolved with a short course of oral steroids. Because of her limited activity, she developed a stage II partial-thickness pressure sore at the midlumbal vertebral body. The pressure sore was clean and the wound bed was pink, with granulation tissue present, minimal exudate, no necrotic tissue, and intact surrounding tissue.
Wound management included daily cleaning with soap and water when assisted with bathing. Mrs. P reported pain at the site as being a 1 or 2 on a pain scale of 0 to 10. She was able to empty and change the ileoconduit pouch with assistance from her son every 3 to 4 hours, including at night. She changed the barrier and pouch every 3 days to avoid leakage. She was able to eat orally without difficulty; however, she had little to no appetite. Her serum albumin concentration was 2.8 mg/dL. She also experienced nausea with the chemotherapy. Unfortunately, she experienced increasing pain in her lower abdomen and required increasing amounts of narcotics. The use of the narcotics caused constipation and bowel obstruction, which was complicated by radiation changes to the bowel resulting from prior treatment.

To assist this patient in the promotion of palliation and comfort, the following measures were advised. Mrs. P was given a large bag to be connected to the ileoconduit pouch at night, to allow for a full night’s sleep for both patient and caregiver. The ileoconduit pouching system was changed to a convex barrier, which decreased the frequency of appliance change to every 5 to 7 days instead of every 3 days. In terms of the pressure sore, the patient and her son were taught pressure relief techniques including side-lying and use of pillows. The son was also taught placement of a hydrocolloid dressing over the wound site and to change this dressing every 3 days. The patient was given a bowel regimen to assist in prevention of bowel obstruction; this regimen included stool softeners, laxatives, and increased fluids. Mrs. P was encouraged to continue her pain medication regimen to maintain comfort. She was given antinausea medication to minimize nausea associated with the chemotherapy.

**Summary**

Skin disorders are both emotionally and physically challenging for patients and caregivers. Cutaneous symptoms may be the result of disease progression (e.g., tumor necrosis, fistula development), complications associated with end-stage disease or the end of life (e.g., pressure ulcers), or simple changes in function of urinary or fecal diversions. All cutaneous symptoms require attention to basic care issues, creativity in management strategies, and thoughtful attention to the psychosocial implications of cutaneous manifestations. Palliative care intervention strategies for skin disorders reflect an approach similar to those for nonpalliative care. Although the goals of care do not include curing the condition, they always include alleviating the distressing symptomology and improving quality of life. The most distressing symptoms associated with skin disorders are odor, exudate, and pain. The importance of attention to skin disorders for palliative care is related to the major effect of these conditions on the quality of life and general psychological well-being of the patient.

**References**

**Key Points**

- **Pruritus** is not a pain state, but it causes considerable distress that affects patients psychologically, physically, socially, and spiritually.
- Treatment choices for pruritus should be made based on the type of pruritus involved and should use both local and systemic measures.
- The management of fever and sweats in palliative care should be focused on comfort measures.

---

**PRURITUS**

Pruritus, derived from the Latin word *prurire*, which means “to itch,” is a common and poorly understood symptom of both localized and systemic disorders (Table 17-1). The difficulties of defining the clinical characteristics of pruritus are in part related to the ambiguities of the available terminology and difficulties in quantifying this subjective disorder. “Itch,” while describing the actual experience of sensory discomfort, is sometimes confused with scratching, the response used to relieve the discomfort. The literature is also less than clear on the distinction between itching and pruritus.1,2 “Itch” is probably best reserved to describe the actual sensory discomfort that may arise in response to a fleeting stimulus or a pathological disorder.1 The term “pruritus,” is generally used to refer to a pathological condition in which the sensations of itch are intense and often generalized and trigger repeated scratching in an attempt to relieve the discomfort. Quantification of itch intensity, which is necessary for both clinical management and intervention studies, usually relies on the same 0-to-10 scale used to rate pain and other subjective symptoms. An assessment can also be made of “itch behaviors,” such as rubbing and scratching, or the physical manifestations of these behaviors, such as the severity and distribution of scratch-induced excoriation.

Although itching is not normally considered a pain state, its neurotransmission parallels that of pain, and the discomfort it causes can be just as distressing as conditions ordinarily considered painful. Words used to describe pruritus include “intense itch,” “stinging,” “burning,” “pins and needles,” “tickle,” “a creeping or crawling sensation,” and “pain.” The particular descriptor used often depends on whether the cause of the itch is primarily cutaneous or neuropathic and, in the case of cutaneous conditions, which inflammatory mediators have been activated. Like persistent pain, persistent itch, especially when generalized, can cause considerable distress, including alterations in mood and

Skin Anatomy

The skin is the body’s first line of defense and its largest organ system. It consists of two layers, the epidermis (outer layer) and the dermis (inner layer), with a basement membrane zone dividing the two. Subcutaneous tissue, consisting primarily of fat and connective tissue, lends support to the neural and vascular systems that supply the skin and contains eccrine glands (ordinary sweat glands) and deep hair follicles.

The cells of the epidermis produce keratin (a fibrous protein), which imparts durability to the skin and protection against real-world frictions, and melanin, which protects against ultraviolet radiation. There are five layers of the epidermis: stratum corneum, stratum lucidum, stratum granulosum, stratum spinosum, and stratum germinativum (the single layer of basal cells attached to the basal membrane). Within these layers are found four major cell types: keratinocytes (which produce keratin), melanocytes (pigment-synthesizing cells), Langerhans’ cells (derived from bone marrow cells, which assist in cutaneous immune responses and produce prostaglandins), and Merkel’s cells (mechanoreceptors).

The dermis separates the epidermis from the subcutaneous tissues and is well vascularized, providing nutrients to the more superficial layers of skin. The two layers of the dermis are the papillary dermis (which contains capillary venules, lymph vessels, and nerve fibers) and the reticular dermis (the thicker layer of the dermis, consisting of collagen bundles interlaced by elastic fibers and ground substance). The cell types found in the dermis include fibroblasts (which secrete enzymes necessary to remodel the connective tissue matrix), macrophages (which synthesize enzymes that enhance or suppress lymphocytic activity and express inflammatory mediators), lymphocytes, and mast cells (which contain among other substances the pruitogenic mediator histamine).

Pathophysiology

Neural innervation separates the self from the nonself, the skin’s sensory innervation must allow for all manner of touch, temperature, and pain sensitivity while at the same time responding to changes in environmental conditions. Receptors for pain, heat, cold, touch, pressure, and pleasure are distributed widely within the skin. These receptors are in turn innervated by a variety of afferent nerve types, including well-myelinated A fibers (which relay sharp pain, proprioception, direction of movement along the skin), myelinated D fibers, and unmyelinated C fibers. Afferent C fibers comprise 70% of all peripheral neurons transmitting to the central nervous system (CNS) and are of three types: C mechanoreceptors, cold thermoreceptors, and C polymodal nociceptors. Maintenance of the skin’s function as a protective barrier and temperature-regulating organ also requires a motor, or efferent, nerve supply. The ongoing turnover and replacement of epidermal cells, which maintains the skin’s function as a protective barrier, requires a rich vascular supply. This vascular supply is in part regulated by sympathetic efferent fibers. The skin’s function as a temperature-regulating system also depends on changes in cutaneous vascularity as well as the function of sweat glands and erector pili muscles (pilomotor muscles are responsible for “goosebumps”). Thermoregulatory sympathetic nerves help to modulate body temperature by either vasodilatation or vasoconstriction and by controlling the function of the sweat glands.

The sensation of itch can arise from either exogenous or endogenous stimuli. Regardless of the origin, evidence suggests that the sensation is transmitted by otherwise inactive nonmyelinated C nerve fibers. Such cutaneous sensory nerves can be activated by a variety of chemical or physical stimuli and serve as the final common sensory pathway for transmission of the itch stimulus. The ultimate sensation of itch, therefore, often provides little information about the etiology or provoking factors of itch. Chemical stimuli include caustic and abrasive substances, which cause skin injury, as well as a variety of potential topical allergens, including additives in perfumes and cleaning products. Physical stimuli that can cause pruritus include sunburn, negative pressure, moving suddenly from cold to heat in the presence of moisture, low-voltage electrical stimulation, and the epicutaneous application of caustic substances. Through uncertain mechanisms, repeated scratching itself can promote itch. Scratching causes lichenification, or thickening of the epidermis, which may decrease the sensitivity of large nerve fibers that may “gate” the perception of itch. The exact mechanisms by which chemical and physical stimuli cause itch are in some instances stimulus-dependent, generally acting either directly on the free nerve endings or indirectly through the release of histamine (from dermal mast cells) or other inflammatory mediators.

As discussed above, the neurotransmission of itch typically begins with activation of the free, or penicillate, nerve endings of unmyelinated polymodal C nociceptive fibers, which lie at the epidermal–dermal junction. The terminal ends of these fibers form a rich arborization throughout the granular layers of the epidermis and dermis. Why some signals carried by these fibers are interpreted as itch and others as burning pain appears to depend on the pattern of neural firing and/or of cocactivation of other nerve fibers. Activated C polymodal nociceptive fibers transmit their signals back to their nerve cells in the dorsal root ganglia and then to the spinal cord to synapse in the substantia gelatinosa of the dorsal horn. After interacting with interneurons within the dorsal horn, fibers ascend in the anterolateral pathways (including the spinothalamic tract) to terminate within the brain stem and thalamus. The role played by the cerebral cortex in the mediation of itch remains undetermined but, as will be indicated below, appears to at least in part inhibitory. In both the laboratory and the clinic, brain injury can result in clinical itching.
The neurochemical mediation of itch begins with activation of the polymodal nociceptive C fibers. These contain neuropeptides such as substance P, neurokinin A, vasoactive intestinal peptide, and calcitonin gene–related peptide.1,3,4 Capsaicin, an alkaloid from the chili pepper plant, typically evokes pain when applied to the mucous membranes or skin, due to release of substance P. When applied at very low concentrations, however, the sensation of itch rather than pain may occur. When chronically applied, capsaicin depletes substance P and, therefore, can block transmission of both itch and pain. Prostaglandins can lower the threshold to chemically induced itch, though prostaglandin antagonists do not typically have antipruritic effects except in certain hematological disorders such as polycythemia vera.15 Other mediators that produce itch are the endopeptidases. These include such enzymes as trypsin, chymotrypsin, bradykinin, kallikrein, and papain, which have been demonstrated to cause pruritus when injected into the skin even in the absence of dermal histamine. Itching powder, or cowhage, which is derived from the legume Mucuna pruriens, contains endopeptidases that cause the sensation of itch.6 One mechanism by which microorganisms, such as bacteria, fungi, and parasites, may cause itching is the release of endopeptidases and other inflammatory mediators.

Serotonin is also an important mediator of pruritus, as revealed by the response of various pruritic states to antiserotonergic therapy. 5-hydroxytryptamine-3 (5-HT₃) antagonists (e.g., ondansetron, granisetron) have been used to palliate pruritus associated with uremia and cholestasis.14,15 The temperature-dependent pruritus seen with polycythemia and lymphoreticular malignancies may also respond to antiserotonergic therapies.

**Etiology**

Pruritus, like pain, is multifactorial in origin and can be a symptom of diverse pathophysiology. Like pain, pruritus can at times serve as a warning sign of external or internal threats to the organism or exist only as a discomforting and unwelcome symptom. Management of pruritus must begin with a thorough assessment of the various etiological causes. Several different classification systems for pruritus have been proposed and are useful in conceptualizing its causes. When no cause can be found, even after a meticulous evaluation, it is referred to as primary, or idiopathic, pruritus. When symptoms are severe and generalized, the patient should remain under continued surveillance for the development of a possible malignancy.16–18 Secondary pruritus can arise from either dermatological or nondermatological causes, and the distribution can be localized or systemic. Acute localized onset of pruritus is less suggestive of systemic disease than is chronic generalized pruritus.

**Secondary Pruritus.** Secondary pruritus can be related to either exogenous agents, such as scabies, insect bites, and fungi, or endogenous factors, for example, atopic dermatitis, psoriasis, and biliary obstruction. Pruritus caused by a specific disease may require medical or surgical intervention. As noted above, itch can arise from a variety of exogenous physical and chemical stimuli, as well as from a large number of endogenous causes. Other endogenous causes for pruritus are not as well understood. In metabolic disorders, malignancies, and conditions of organ failure, pruritus may be due to hormonal imbalance, excessive production of cytokines, or build-up of metabolic by-products. Some of the most common causes of pruritus in the palliative care setting include senile pruritus, cholestasis, skin dermatoses, drugs, uremia, and psychogenic etiologies.19

**Various Common Clinical Situations**

**Atopic Dermatitis.** Pruritus in atopic dermatitis (AD) arises from the release of proinflammatory cytokines from mast cells and keratinocytes.20 It is postulated that there is a dysfunction of bone marrow–derived cells migrating to the skin rather than an intrinsic cutaneous defect. Lymphocytic infiltrates of AD consist of T-helper cells. Both the Langerhans’ cells and macrophages found in AD lesions have surface-bound immunoglobulin E (IgE). The patterns of cytokine production are also distinctive, due to the presence of interleukin-4 (IL-4) with the acute inflammatory phase and IL-5 and eosinophil infiltration with chronic inflammation.20

**Cholestatic Jaundice.** In cholestatic liver disease, the accumulation of bile salts is presumed to be a causative factor in pruritus, though an association with bile levels in the skin and blood has not been consistently demonstrated.21,22 Moreover, the response of pruritus to a variety of agents, each with differing mechanisms of action (e.g., ondansetron, rifampin, opiate antagonists, propofol, cholestyramine, norethandrolone, etc.) renders the primary causative factor even more obscure.23–27 More recent evidence points to the accumulation of pruritogenic endogenous opiates.28–30

**Opioid-Induced Pruritus.** Opioids can cause pruritus, whether administered by the systemic, intraspinal, or intracisternal route. Clinically, itching is most commonly seen after intrathecal administration; then, typically, it is initially localized and most severely experienced in and about the face. Epidural administration, due to the higher systemic levels of opiate achieved with this route, tends to cause more generalized itching. Among opioid-naïve cesarean section patients, as many as 60% to 80% receiving epidural morphine report pruritus, with more than half of these requiring treatment.31,32 The occurrence among palliative care patients, most of whom are not opiate-naïve at the time of epidural placement, is
considerably less, suggesting that tolerance to the pruritogenic effects of opiates develops with continued opioid exposure. The mechanisms for opioid-induced pruritus are several. Opioids are known to trigger mast-cell degranulation with histamine release, which probably accounts for the pruritus seen with systemic opioid administration. Opioid antagonists can attenuate histamine-induced itch unrelated to opioid administration, suggesting that endogenous opioids play an intermediary role in some forms of chemically induced pruritus.\textsuperscript{33} Morphine, which appears to cause greater histamine release than fentanyl, meperidine, or oxymorphone, is most frequently implicated in opioid-induced pruritus. Changing to an alternative opioid (opioid rotation) may be a successful management strategy.\textsuperscript{34–38} The fact that pruritus can be caused by either intrathecal or intracisternal opioid administration also speaks to a direct pruritogenic effect of opioids on the CNS.

**Pruritus Associated with Lesions of the Central Nervous System.** Pruritus may also arise from disorders of the CNS (e.g., cerebrovascular accident pruritus).\textsuperscript{10} Cases of hemipruritus have been described following stroke and with multiple sclerosis (MS). Phantom itch can occur in the amputated limb.\textsuperscript{40} Paroxysmal itching may also result from nerve root demyelination in MS.\textsuperscript{40,41}

**Anorectal Pruritus (Pruritus Ani).** While sometimes mistakenly viewed as a discrete diagnosis, anorectal pruritus is a common symptom of a large number of disorders affecting the lower colorectal area. Common etiologies include hemorrhoids, pinworms and other parasites, fungal infection, rectal irritation and dryness from detergent soaps, rectal seepage, and cryptitis from undigested food particles. Premalignant conditions, such as Bowen’s disease and Paget’s disease, may also present with these symptoms. In one reported series, 16% of 109 patients evaluated for pruritus ani were found to have a neoplastic lesion in the anorectal area.\textsuperscript{42,43}

**Uremia.** Pruritus can be a disabling symptom of end-stage renal disease and is not relieved by dialysis. Between 80% and 90% of patients undergoing hemodialysis suffer from this symptom.\textsuperscript{44} As with many systemic causes of pruritus, the pathogenesis is poorly understood. Recent studies have shown affected patients to have high plasma histamine levels. These levels, as well as clinical pruritus, were significantly reduced by therapy with recombinant erythropoietin, the treatment reaching its maximal efficacy after 3 to 4 weeks.\textsuperscript{45} Other potential causes of pruritus include secondary hyperparathyroidism, uremic and other forms of polyneuropathy, xerosis, and hypervitaminosis A.

**Evaluation of the Patient with Pruritus**

Evaluation of pruritus should be thorough and systematic, applying the same principles used when assessing pain. Quantify as much as possible any physical findings as well as subjective responses to the pruritus (e.g., distress associated with the itch based on a scale of 0–10, with 0 being “no distress” and 10 representing “severe distress”).

**Location.** It is important to recognize whether the itch reported by the patient is generalized throughout the body, focal to a single region, or more widespread but in a particular pattern. Itching around skin creases of the wrists, axilla, and intertriginous areas, as well as the umbilicus and nipples, suggests scabies infestation. Anogenital itching may be due to contact dermatitis (e.g., from menstrual or continent pads, deodorants, washing products), Candida or other fungal infection, other infestations, or potentially psychogenic causes. Localized dermatitis, for instance, with a dermatomal distribution, may indicate prior herpes zoster infection or other segmental neurological abnormality. Generalized pruritus may arise from a large number of causes, including organ failure, endocrinopathy, or dry skin.

**Presence or Absence of Rash.** Pruritus resulting from systemic disease is seldom characterized by a rash, though with histamine and serotonin release, a mild flush may be present. It is important to distinguish between a true rash and the stigmata of frequent scratching, including excoriations and dermatographia. Focal rash may indicate contact sensitivity, evolving skin infection, or dryness of skin with associated flaking.

**Quality of Symptoms.** The common itch consists of an irresistible and persistent tickling sensation, which is usually, at least transiently, relieved with scratching. In addition to bearing the tickling sensation common to the itch experience, itch from irritant dermatitis and herpes zoster typically has a burning quality. Actual pain may coexist with itch in herpes zoster and other neuropathic lesions or arise from the trauma of repeated scratching.

**Aggravating and Alleviating Factors.** Topical application of heat often worsens itching, whereas cold diminishes the sensation. Worsening of pruritus after a hot shower is typical of Hodgkin’s disease, myeloid metaplasia, and polycythemia vera. Consumption of alcohol may also induce itching in these conditions.

**Laboratory Evaluations.** Laboratory tests are used most commonly in cases where the manifestation of pruritus is of the generalized type. In such cases, the evaluation should be directed towards an underlying systemic cause. Laboratory tests should include a complete blood count (with differential leukocyte count), and liver, renal, and thyroid panels.\textsuperscript{19}

**Treatment/Management of Pruritus**

**Local Dermatological Measures**

**Topical Treatment.** Dry skin (xerosis) is common in patients who have undergone chemotherapy or radiation therapy. Xerosis arises either as a direct effect of therapy or as a manifestation of anorexia, dehydration, impaired nutrition, or
weight loss because the skin becomes more vulnerable under these conditions to everyday traumas. 46

Xerosis is also a common cause of pruritus in the aged. Other causes are related to reduced activity of the sebaceous and sweat glands, thinning of the skin, decreased subcutaneous tissue padding, and alterations in skin elasticity. Hydration of the skin is essential and can be accomplished by soaking in a warm bath for 15 to 20 minutes. The area should be patted dry, followed by application of an occlusive or moisturizer (Table 17-2). This is referred to by Nicol and Boguniewicz246 as the "soak and seal" method and can relieve dryness by trapping moisture in the skin. Vaseline is considered an occlusive but must be used after hydration because it does not contain moisture. Moisturizers can be classified as lotions, creams, or ointments. Lotions can potentially be more drying to the skin since they contain more water and evaporate more quickly. There are a number of moisturizers (among them Eucerin, Aquaphor, Vanicream, Moisturel, and Cetaphil) available in large containers that are alcohol- and fragrance-free. Among patients for whom cost is a treatment-limiting factor, a cooking shortening, such as Crisco, can be an inexpensive alternative moisturizer. Moisturizers and occlusives should be applied several times per day. Patients should also be advised to wear clothing that is loose fitting, less irritating, and minimizes retention of heat and sweating to help reduce the itch sensation. The best type of fabric to wear is cotton clothing. 47

For patients with pruritus, skin cleansing is important, especially if there are skin excoriations due to scratching. Many patients additionally seek relief by bathing or skin washing. The skin cleansers used in these situations should have a neutral pH and minimal defatting activity. Examples of such products include Dove, Oil of Olay, Basis, and Aveeno. Oatmeal baths and cold packs can be used to dry vesicles and relieve itch. Other topical agents such as calamine and topical Benadryl contain an antihistamine, which soothes and dries vesicles and decreases scratching. Camphor, phenol, and pramoxine may have local anesthetic properties, and menthol, a counterirritant, gives the impression of a cooling effect to the skin. 48

A morphine- and lidocaine-based cream has been used in our clinical practice for pruritus described as burning and painful. Topical applications have been used for bullous pemphigoid lesions associated with graft versus host disease, cutaneous skin lesions associated with chest-wall recurrence of breast cancer, and macerated rectal skin from persistent seepage. The preparation, when applied three times a day over affected areas, was highly effective at decreasing pain and pruritus. Creams compounded with antidepressants, such as doxepin (Zonalon), may decrease itch by local inhibition of H1 and H2 receptors, as well as through antiserotonergic effects. 4, 20

Topically applied corticosteroids can reduce inflammation and itching associated with urticaria and other acute conditions but are generally not indicated for chronic use. Key considerations when prescribing topical steroids are the potency of the product (high to low potency), the vehicle used (lotion, cream, ointment, solution, gel), and the area of application. Examples of high-potency steroids include betamethasone dipropionate (Diprolene 0.05%) ointment/cream and desoximetasone (Topicort 0.25%) ointment/cream; mid-range preparations include triamcinolone (Kenalog 0.1%) ointment/cream and betamethasone valerate (Valisone 0.1%) ointment; hydrocortisone (Hytone 2.5%) and 1% ointment/cream/lotion represent low-potency preparations. 20 The side effects from prolonged use may include thinning and hypopigmentation of the skin, secondary skin infections, acne, and striae. If high-potency topical steroids are used under occlusive dressings, greater skin and systemic absorption can occur, which increases the likelihood of localized atrophy and systemic side effects (e.g., Cushing’s disease, cataracts, hyperglycemia, and avascular necrosis). 20, 49, 50 In the same manner, ointments are more occlusive than other vehicles and, therefore, may be associated with a higher skin penetration as well as a greater likelihood of side effects upon prolonged use. In hot, humid conditions, ointments may also cause folliculitis, thereby increasing pruritus. Under these conditions, creams may be a better option. Topical steroids should generally not be applied more often than twice a day. Hydration of the skin before each application will promote absorption through the stratum corneum, thereby improving local absorption and efficacy. 50 It is typical to start with a high-potency preparation and to move to a lower-potency agent as the dermatitis/pruritus improves. 49

**Antifungal Treatment.** The most frequent superficial fungal infection of the skin is Candida albicans. Typical areas of infection involve the inframammary areas, inguinal folds, and vulvovaginal areas, with pruritus being a common manifestation. Patients predisposed to candidiasis include those who are obese and have overlapping skin folds, those who are immunosuppressed, are on broad-spectrum antibiotics, are receiving corticosteroids, or have diabetes. Skin involvement in the inframammary or inguinal folds often appears as a creamy white layer, but gentle removal of this layer may reveal an erythematous base, with areas of maceration and even papules and pustules. Vulvovaginal infections will have a cheesy vaginal discharge, with itching and excoriation of the vulva.

Topical antifungal agents in use fall into three classifications: the polyene group (nystatin), the azole group (ketconazole, fluconazole, itraconazole), and the allylamine/benzylamine
group (ciclopiroxolamine, terbinafine). The allylamine/benzalmine group is the newest generation of antifungals. They have greater bioavailability and a high cure rate with a shorter duration of treatment. To prevent recurrence, antifungal treatment should continue for 5 to 7 days after signs of infection have resolved. Ketoconazole should not be used in individuals with sulfite sensitivity. Some antifungals are prepared with corticosteroids; however, these should be avoided to prevent side effects from the corticosteroids.

Fungal infections not responsive to topical therapy will require systemic treatment. Systemic antifungals include griseofulvin, the azoles, and the allylamines. Gastrointestinal distress, headaches, exanthema, and liver toxicity (griseofulvin and fluconazole) are common side effects.

Tar preparations may reduce inflammation and limit the use of topical steroids in chronic pruritus/dermatitis. They may be used at night and washed off in the morning. Tar products are less costly; however, the smell and staining that occur with these products make them less than desirable.

Phototherapy with ultraviolet A may be an option for some individuals. Initially, treatments are given three or four times per week and, after several weeks, may progress to weekly. An oral preparation of psoralen before phototherapy may also be used for a wide range of disorders from AD to renal disease. Side effects include sunburn and an increased risk of skin cancer.

Systemic Measures

**Opioid Antagonists.** Naloxone hydrochloride (Narcan) is effective for relieving pruritus related to systemic and intraspinal opiates. Infusion of naloxone at an hourly dose of 0.25 mg/kg was successful at relieving pruritus in patients receiving a continuous morphine infusion and appeared to enhance rather than diminish postoperative analgesia. Naltrexone, an agonist–antagonist analgesic, has also shown efficacy under similar conditions. Naltrexone and nalmephene are oral agents, with a longer half-life than naloxone, that have been used in the treatment of pruritus associated with cholestasis, uremia, AD, and urticaria. It is not known whether all centrally acting opioid antagonists are equal in their antipruritic effects. When naltrexone was used for pruritus in a patient with mycosis fungoides after initial success, their antipruritic effects. When naltrexone was used for pruritus in a patient with mycosis fungoides after initial success, they were continued for the treatment of pruritus except by those experienced in their use.

**Antidepressants.** Doxepin, amitriptyline, nortriptiline, and imipramine have been used in the treatment of numerous neurogenic pain states. Pruritus is frequently a comorbid feature of neurogenic pain, and anecdotal reports suggest that the same tricyclic antidepressants that are efficacious in certain forms of neurogenic pain may also be beneficial in treating pruritus. As the most antihistaminic of the group, doxepin may be the most effective. Mirtazapine also has potent H1 antagonism, as well as antisero-tonergic effects at both the 5-HT2 and 5-HT3 receptors. Since antagonism at each of these individual receptor types has been associated with antipruritic effects, mirtazapine may possess a theoretical advantage in pruritus treatment. The SSRI Paroxetine (paxil) has been shown to be effective in patients with generalized pruritus during terminal illness. The addition of a 5-HT1 agent such as ondansetron (Zofran) and mirtazapine may enhance the efficacy of paxil in this setting.

**Propofol.** Subhypnotic doses of propofol have been successfully used in the treatment of pruritus resulting from neuraxial administration of opioids and cholestasis from pancreatic...
neoplasm, hepatic and bile duct metastasis, and primary biliary cirrhosis. Patients achieved rapid symptomatic control following both single injections and continuous low-dose infusion. While the mechanism of action is unclear, the effect was unrelated to sedation.

Anticonvulsants. In general, anticonvulsant agents have not been investigated for utility in the treatment of pruritus. Several anticonvulsant agents, such as carbamazepine and gabapentin, are of established clinical efficacy in the treatment of a variety of neuropathic pain syndromes. When pruritus complicates a known neuropathic disorder (e.g., postherpetic neuralgia), a therapeutic trial of one of these agents should be considered.

Other Agents. Ondansetron, a 5-HT3 antagonist, has been used in cholestatic, uremic, and opioid-induced pruritus. Benzo- diazepines, such as lorazepam and alprazolam, may be helpful in relieving itch if anxiety is also present. Benzodiazepines are not suggested for long-term use.

</tbody>
</table>
Sensory modulation can be accomplished through counterirritants, heat or cold, and transcutaneous electrical nerve stimulation (TENS). The Roman physician Scribonius Largus used the voltages of certain fish (electric rays and torpedo fish) in 47 A.D. for treatment of gout and headaches. With the advent of the battery, TENS units that provided a more reliable source of current were developed. When applied directly over the pruritic area, surrounding area, or acupressure points, TENS may block transmission of polymodal nociceptive C fibers, thereby blocking pain and pruritus.

Capsaicin depletes substance P when applied repeatedly to the mucous membrane or skin, decreasing both pain and itch sensations. When given in low concentrations, the stinging, burning itch may initially be exacerbated. The gate control theory of pain states that impulses carried by noxious stimuli to the spinal cord via thin myelinated and unmyelinated fibers are blocked at the dorsal horn by stimulation of larger-diameter myelinated nerve fibers by pressure, vibration, or a TENS unit. Thick nerve fibers have a lower threshold than thin fibers and adapt more readily. No adaptation takes place in the large fibers when scratching or vibration occurs. This may explain why scratching or rubbing the affected part sometimes relieves mild to moderate pain.

Nonpharmacological Measures. In a palliative care setting, most patients are in the terminal phase of their disease. Pruritus during this phase of illness is primarily a result of changing organ functions. For example, liver and kidney function may be deteriorating. Thus, systemic therapy might be more toxic to patients in the terminal phase of their illness. Hence, it is important to attempt nonpharmacological antipruritus measures to minimize further injury to organ functions and to maintain quality of life (Table 17–4).

**CASE STUDY**

**Ms. S, a Patient with Pruritus**

Ms. S is a 75-year-old woman with a history of non-Hodgkin’s lymphoma, cervical cancer, breast cancer, chronic renal failure, hypothyroidism, hypertension, and seizure disorder. She was treated for a disseminated herpes zoster infection diagnosed 3 months earlier that involved several dermatomes (T2–L2). Ms. S was seen in clinic for complaints of pruritus in the right posterior chest that had been present for 3 months and thought to be a postherpetic neuralgia. The patient described the pruritus as a burning, unrelenting itch and stated she was “ready to give up.” The following medications were prescribed and reported to be ineffective: amitriptyline (Elavil) 20 mg at bedtime (qhs), hydroxyzine (Atarax) 25 mg three times a day (tid), diphenhydramine (Benadryl) 25 mg tid po, and doxepin cream 5% to the affected area four times (qid) a day. Nondrug interventions included ice pack to the back for 20 min tid. Famotidine (Pepcid) 20 mg twice a day (bid), prednisone 20 mg bid, and triamcinolone acetonide (Kenalog) cream 0.025% topically applied tid were also used, again without relief. The patient was admitted to the hospital for cellulitis in the right arm, presumably a secondary bacterial infection resulting from the scratching, and was given cefazolin (Ancef) IV.

The patient denied any contact with pets, no new or changed soap/detergents, cosmetics, body lotions/creams, medications, and no exposure to scabies or to new foliage. She denied pruritus in any area other than her back.

Clinical evaluation: a frail, elderly woman who appeared uncomfortable and at times restrained herself from scratching. No vesicular eruptions were noted. Dry blood and numerous scratch marks are present over the posterior thorax. Three raised erythematous areas were noted, in the right scapular, lower thorax, and lumbar areas. Skin turgor was good. There was no alopecia, and no lymphadenopathy in the head/neck, supraclavicular area, or axilla. There was no evidence of a rash, infection, or tracks. Blood urea nitrogen and creatinine were stable, and thyroid function tests were within normal limits. The impression was that this woman with a history of herpes zoster infection had developed postherpetic neuralgia.

Ms. S’s pruritus was treated as a postherpetic neuralgia, and a prescription for mexiletine (Mexitil) 150 mg bid was given with instructions to take with food to minimize gastrointestinal side effects. Ms. S was asked to titrate by one pill (150 mg) every 5 days to a total of 300 mg tid. Amitriptyline (Elavil) 10 mg was prescribed with instructions to take every evening at 8:00. By taking this medication earlier in the evening, the patient was less likely to feel “hungover” in the morning.

The patient reported improvement in the “itchiness and discomfort” in her back once the mexiletine was started; however, she developed a tremor that she noted while in church. The patient became frightened and stopped the
medication. Ms. S was evaluated in an urgent-care clinic by an on-call physician. Upon examination, an essential tremor was diagnosed and the patient was advised to restart the mexiletine at 150 mg tid for 24 hours and then to increase to 300 mg tid. Ms. S was reevaluated later that week and reported “dizziness” when taking mexiletine 300 mg tid. She stopped the amitriptyline at night and continued to report relief of the pruritus with the use of this drug. The patient was asked to decrease the mexiletine to 150 mg tid and to restart the amitriptyline 10 mg qhs. The patient called several days later to report that the pruritus was not controlled at this dose and that she was afraid to increase the dose because of side effects (i.e., tremor). The patient was seen in clinic, and it was decided that since the mexiletine was the only medication that provided any relief of her symptoms, the dose would be adjusted again to 150 mg in the morning and evening and 300 mg at hs; propranolol (Inderal) 10 mg tid was added to decrease the tremor.

### Nursing Implications

#### Assessment

1. Describe and document the color, characteristics, and size of any lesions.
2. Obtain a thorough history of any new products (detergents, lotions, soap), exposure to new pets, recent travel and outdoor exposure, or any new medications.
3. Obtain a thorough patient and family history of allergies (e.g., food or seasonal), treatments previously used and their success, travel, hikes, and any exposure to known infectious agents/insect bites. Do other members of the family or others with whom the patient has had social contact have pruritus?
4. What has been the general health of the patient during the several weeks preceding the development of pruritus?
5. A skin biopsy may be required to determine the etiology of the pruritus.

#### Management

1. Teach safety measures with use of sedating antihistamines, such as not driving or operating potentially dangerous equipment until tolerance to the sedating effects of these medications has been established.
2. Psychological support is needed for any new diagnosis of malignancy.
3. Educate patients concerning the proper use of topical medications and the potential side effects.
4. Frequently assess the skin in pruritic areas for the presence of any secondary infections.

---

**FEVER**

Fever is defined as a rise in normal body temperature (above 37° ± 1°C), as a temperature ≥38°C for three consecutive readings performed 1 hour apart, or as one reading ≥38.5°C.73 Fevers can be a result of inflammation (including malignancy), infection, immunological disorders, hypermetabolic states (e.g., thyrotoxicosis), hyperthermia, heat stroke, or, uncommonly, disorders of the CNS (e.g., cerebral stroke) (Table 17-5). Febrile illnesses have been recorded in the medical literature as far back as Hippocrates (5th century b.c.e.), though it was not possible to actually measure body temperature until the development of the thermometer in the mid-19th century.74,75 Determining the etiology of a fever is often essential to providing the most appropriate treatment of this symptom as well as of its underlying causes. Deciding when to treat the actual symptom of fever depends to a great extent on the symptoms associated with it (e.g., tachypnea, tachycardia, hyperhydrosis, feeling of dissipation, fatigue), age, general medical condition, any comorbid conditions or diseases, and the goals of care relative to the patient’s stage of illness. For example, the treatment of fever and associated tachycardia in an older patient with a known history of advanced coronary artery disease but few other comorbid illnesses may itself be life-saving. Treating fever usually provides improved patient comfort. However, treating fever may at times have the unintended effect of inhibiting immunological responses mounted as a means of defense against infectious pyrogens.75 To what extent such inhibitory responses are of clinical significance is largely unknown.

In the setting of palliative care, decisions on treating an infectious etiology of fever can at times trigger controversy since the treatment may prolong the dying process. How aggressively infection should be treated at the end of life depends on the factors listed above and the plan of care agreed upon by the patient, family, and health care professionals.

#### Pathophysiology

The body’s thermoregulatory system is controlled by the preoptic region of the anterior hypothalamus. Under ordinary circumstances, the hypothalamus maintains the core body temperature by establishing a thermal set-point. This set-point, analogous to a thermostatic control, may be affected by the presence of various pyrogens, or fever-causing substances. Pyrogens may be produced by and released directly from infectious pathogens (bacteria, viruses, or fungi). These are typically called “exogenous” pyrogens. Pathogenic agents may also stimulate the release of endogenous pyrogens from the immune system. The four best recognized endogenous pyrogens are IL-1, IL-6, tumor necrosis factor-α (TNF-α), and interferon (IFN). Systemic release of either exogenous or endogenous pyrogens can trigger the fever response by elevating the hypothalamic set-point so that compensatory temperate lowering mechanisms are not activated until higher-than-normal
temperatures are reached. At this time, it is not known if peripherally released cytokines cross the blood–brain barrier to directly influence the hypothalamic set point, or whether this process occurs through other cytokine mediators or even neural means. At the hypothalamic level, prostaglandins, especially prostaglandin E₂, appear to play an important role in establishing the hypothalamic set-point. It is presumably through these inhibiting prostaglandin mediators that aspirin and certain other antipyretic agents work. Regardless of the actual mechanism, the hypothalamus continues to regulate body temperature, though this regulation is now around a higher set-point. When an antipyretic is given or the pyrogen level is decreased, the hypothalamic temperature is reset back to normal. Temperatures above 41°C suggest that the source of fever may be either abnormal heat production (as in malignant hyperthermia) or problems with heat dissipation (as in heat stroke).

Phases of Fevers

There are often three stages of a fever. The “cold stage” occurs when there is a physiological discrepancy between the hypothalamic set-point, now at a higher level, and the existing body temperature. In response, hypothalamic mechanisms signal for peripheral vasoconstriction to occur, which diminishes cutaneous heat loss, and for shivering, which generates heat through increased muscle activity. The “hot stage,” or febrile phase, occurs when body heat is maintained at a higher-than-normal level due to the higher set-point of hypothalamic thermoregulation. During the febrile stage, symptoms often include flushing of the skin, increased sense of thirst, sensation of increased body warmth, lethargy, and restlessness or irritability. Less commonly seen CNS manifestations include hallucinations and seizures, though the latter are seen almost exclusively in young children. During febrile states, the basal metabolic rate is increased as tissue metabolism and oxygen requirements increase by 10% to 13% for each 1°C increase in body temperature. Associated physiological changes include tachycardia with an increase in cardiac output and workload.76,77 Decreases in the level of pyrogen produced or administration of an antipyretic at least temporarily resets the hypothalamic set-point. During the defervescent stage, or stage 3, heat dissipation is increased due to vasodilatation and sweating, causing an increase in evaporative skin cooling.77,78 Heat-generating mechanisms (e.g., shivering) are inhibited, and the body temperature falls back within the normal range.79,80

Etiology

Immunological Responses. Blood products and certain medications, as well as allergic reactions and connective tissue disorders, liberate substances which, in turn, activate release of endogenous pyrogens, the three best recognized being IL-1, IL-6, TNF, and IFN. A variety of secondary immune reactions may trigger the release of pyrogens, including anaphylactic reactions (e.g., asthma), cytotoxic reactions (e.g., blood-transfusion reactions), immune complex–mediated reactions (e.g., serum sickness), and delayed hypersensitivity reactions (e.g., contact dermatitis and allograft rejection). Primary immune disorders that may be associated with a fever include systemic lupus erythematosus, giant cell arteritis, and rheumatoid arthritis.

Infections. Infectious pathogens elaborate pyrogens, such as bacterial lipopolysaccharides, which, in turn, promote the release of endogenous pyrogenic cytokines by stimulating the body’s immune and other defensive reactions. The principal origins of these cytokines are activated monocytes, macrophages, and lymphocytes, which are recruited to respond to the infection. Endogenous pyrogens can also be produced by endothelial cells and fibroblasts.

Of pathogens found in new fevers, 85% to 90% are of bacterial origin. Common origins of bacterial infections in cancer and immunosuppressed patients include the breakdown of skin integrity and mucosal barriers due to multiple venipunctures and lines or catheters, other invasive procedures, decubitus ulcers, cutaneous infections including herpes zoster, and mucositis. Bacteria, as well as other pathogens, induce the production of endogenous pyrogens in macrophages and monocytes. These pyrogens include TNF-α and IL-1β. Release of these substances into the inflammatory mix in turn stimulates the cascade of other cytokines, including IL-1, IL-6, and the prostaglandins.73

Increasing body temperature can itself increase phagocytic activity and affect the type and amount of pyrogenic cytokine released.75 Although fever may contribute in this fashion to stimulation of the immune system, the tachycardia and hypermetabolism caused by the fever can prove fatal in an individual who is immunocompromised, in advanced cancer patients, and in those with acquired immunodeficiency syndrome (AIDS).76,79,80

Inflammation. Inflammation occurs with cellular damage due to cytotoxic agents, trauma (including surgery), radiation therapy, or exposure to heat. Fibroblasts and endothelial cells, as well as macrophages, release endogenous pyrogens, such as IL-1, IL-6, and TNF.73,74,77 Postoperative fluid collections and large internal hematomas are therefore common causes of fever in the surgical patient. Although circumscribed superficial inflammation rarely causes significant fever, inflammation can predispose to secondary infection and a febrile state.76,79,80 Radiation therapy, for example, can cause fevers through several mechanisms. First, immunocytes and endothelial cells damaged by radiation may release endogenous pyrogens. Second, radiation therapy may alter skin integrity (dry and moist desquamation) and damage mucosal barriers, thereby increasing the patient’s predisposition to infection. Infection may also be associated with radiation-related myelosuppression when the radiation field includes the primary sites of blood cell production, such as the sternum, long bones, and iliac crests.81–83 Finally, cranial radiation may cause temporary perturbations in the hypothalamic set-point.

Vascular causes of fever may include thrombophlebitis with or without pulmonary emboli, and regional or systemic tumor-associated vasculitis. The cause of fevers in these settings is thought to be release of pyrogens from phagocytic and endothelial cells. Several cancers, especially lymphomas and gastrointestinal malignancies, are associated with a higher-than-expected risk for developing deep-vein thrombosis. It is not uncommon, in fact, for fever to be the earliest sign of thrombophlebitis. In one study of pulmonary emboli, approximately 18% of the patients had malignancies, 54% had a fever >37.5°C, and 19.6% had a fever >38°C.84

Even in the absence of vascular inflammation, fever may be the presenting symptom of many malignancies, including Hodgkin’s lymphoma, bronchogenic carcinoma, breast cancer, non-Hodgkin’s lymphoma, and multiple myeloma. Fevers related to tumors may be associated with the release of pyrogens, such as TNF-α and IL-6, either directly from the tumor or from tumor-reactive hypersensitivity reactions.73,76,77
Pulsatile release of tumor pyrogens can cause a waxing and waning of fever, which correlates with disease activity. The naproxen test has been used as a diagnostic tool to differentiate between a neoplastic fever and a fever associated with an infection. Chang and Gross reported complete response of neoplastic fevers to naproxen within 24 hours of starting the drug, whereas no patient with an infectious fever showed any improvement. It was postulated that the fever suppression was related to the interference/suppression or release of humoral factor(s). The specificity of this test is uncertain, and the possibility of infection should not be dismissed on the basis of this test alone. Other noninfectious etiologies, such as allergic reaction, drug toxicity, and adrenal insufficiency, also need to be considered.

**Blood Transfusions.** Allergic responses to white blood cells in blood products may be avoided by using irradiated blood products, removing white blood cells from blood (leukapheresis), or premedicating with antihistamines, hydrocortisone, and/or antipyretics.

**Medications Associated with Fevers.** Certain medications may be antigenic; that is, they are interpreted by the body as a foreign substance, thereby initiating an allergic or immune response with accompanying fever. The categories of drug most often associated with a febrile response include antibiotics, cytotoxic agents, cardiovascular drugs, and biological therapies such as the interferons and interleukins. The classes of antibiotics most commonly associated with fevers are the penicillins, cephalosporins, and certain antifungals, such as amphotericin. Cytotoxic drugs such as bleomycin trigger a fever in 25% of individuals, and anaphylaxis results in 1% of cases.

**Hemorrhage.** Gastrointestinal bleeding may result in fever within 24 hours, which may last a few days to a few weeks. Although this has been mentioned in the literature, no clear explanation has been offered, but fever may be related to the release of IL-1 from the damaged gastrointestinal mucosa.

**Neutropenia.** Neutropenia is defined as a polymorphonuclear neutrophil count of 500/mL or less, which may arise from decreased production of white blood cells (myelosuppression from chemotherapy or radiation therapy or tumor infiltration of bone marrow with inhibition of white blood cell production) or increased loss of white blood cells (usually through an autoimmune process). Of patients with neutropenia, 50% to 70% experiencing a fever will die within 48 hours if left untreated because of rapidly progressive sepsis.

**Miscellaneous Factors.** Several general medical problems can be identified as contributing to fever (see Table 17-5). Dehydration limits the body’s compensatory response of heat loss through sweating. Severe obstipation has been associated with fever, due possibly to associated dehydration or ischemia of the bowel, causing a local inflammatory response. Hospitalization itself is a frequent cause of infection and fever, probably because of the frequency of procedures, such as venipuncture and the placement of IV catheters, which violate the integrity of skin defense mechanisms. Nosocomial infections account for more than 80% of infections in cancer patients.

**Opioids.** Opioids have been found to cause a flush (vasodilation) and sweating, especially involving the face, but have not been associated with fever. Meperidine hydrochloride (pethidine hydrochloride) in combination with a monoamine oxidase inhibitor can cause hyperpyrexia, muscle rigidity, CNS excitability, or depression that can be severe or fatal. Abrupt opioid cessation results in withdrawal symptoms, including restlessness, rhinitis, abdominal pain, and fever. Withdrawal from benzodiazepines may also cause a fever.

**Clinical Evaluation**

**Patient History.** A thorough history must be obtained to determine if there are coexisting symptoms suggestive of a urinary tract infection, upper respiratory infection, or any exposure to a person with infection or who has had a live-virus vaccination. A bowel history should be conducted to rule out constipation. If the patient has cancer, when was the last surgery? When was the last course of chemotherapy or immunotherapy? When was the last course of radiation therapy? Is there any history of blood transfusion within the preceding 6 months? It is important to determine the pattern of the patient’s fevers, the time of day they occur, and the number of temperature peaks over 24 hours. In patients receiving end-of-life care, the focus of the treatment plan is palliation of symptoms. Determining the source of the fever will guide the clinician as to the appropriate intervention. If the patient is severely constipated, laxative-induced evacuation may not only reduce the fever but also improve nutritional status and eliminate or reduce nausea, if present. Treating a urinary infection may also improve comfort, promote rest, and improve cognition. Use of oral antibiotics to treat a urinary tract or upper respiratory infections may be appropriate to palliate symptoms, such as the distress that may accompany tachypnea, tachycardia, or shaking chills. Antibiotics are used in this manner to palliate symptoms due to infection rather than to eradicate the infection properly. If antibiotic therapy causes increased physical distress in the form of pruritus, drug-induced fevers, or nausea and vomiting, the role of antibiotic treatment needs to be reevaluated, to keep the focus of care on quality-of-life issues. As with all palliative treatments, it is important to routinely reassess goals with the patient and family to be certain that everyone is in agreement.

**Physical Examination.** Since common sites of infection include the skin, respiratory tract, urinary system, perianal region, oral cavity, and sinuses, a comprehensive evaluation for infection should not overlook any of these sites. In chronically ill and emaciated patients, special attention should be paid to the skin overlying bony prominences as well as the perineal and perianal regions, evaluating for decubitus lesions and other areas...
of skin breakdown, necrotic tumors, and/or infection. If the patient has an IV line, central catheter, or other central venous access device (e.g., Porta-Cath), these need to be carefully evaluated for signs of infection. Decisions on the appropriateness of blood and sputum cultures and radiographic tests need to be made on a case-by-case basis, depending on the patient’s status and the likelihood that test results will lead to a meaningful therapeutic intervention. This said, performance of a urinalysis is noninvasive and inexpensive and can provide information leading to straightforward therapies offering symptom relief.

Management of Common Sources of Skin Infection in End-of-Life Care

There are several interventions nurses can initiate to manage skin infections based on the location, characteristics of the affected area, and organism(s) involved. Dakin’s solution is composed of bleach, sodium bicarbonate, and sterile water. It can be prepared as a 0.25%, 0.5%, 0.75%, or full-strength solution, depending on the contamination of the wound, and may be used to irrigate or pack wounds contaminated with *Pseudomonas*. Clean, healthy skin should not come in contact with Dakin’s solution because it is extremely irritating.

Hypertonic saline gels (Panafil) can debride thick, necrotic eschar on a decubitus without surgical intervention. Morphine (powder or concentrated solution) is added to commercially prepared ointments and substances used for wound healing, such as Silvadene and lidocaine, and to DuoDERM powder to pack inside wounds. These mixtures may be helpful in reducing secondary skin infections as well as promoting comfort, and can be used to pack a venous stasis ulcer, decubitus, or fungating lesion. Fungal infections, generally characterized by a foul odor, maceration of the skin, and occasionally superficial bleeding, are commonly seen in the intertriginous areas (infra-mammary and inguinal folds). Daily cleansing with soap and water, thorough drying of the affected area, and use of antifungal powder or lotion (nystatin, clotrimazole) can be applied twice or three times a day until healed.

Treatment of Fever

Comfort should be the primary goal for the dying patient with a fever. Treatment should be initiated with antipyretics, such as acetaminophen, aspirin, or ibuprofen, which are the only drugs approved by the Food and Drug Administration for this purpose.

Acetaminophen can be administered in tablet, liquid, or suppository form. For tumor-related fever, a nonsteroidal antiinflammatory drug (NSAID) may be especially beneficial. The presence of thrombocytopenia may be a limiting factor in the selection of NSAIDs. The specific cyclooxygenase-2 (COX-2)–inhibiting antiinflammatory agents, such as celecoxib (Celebrex), may in certain instances be preferred in this setting.

Cooling measures, such as a tepid cloth to the patient’s forehead, may be comforting; otherwise, cooling measures (such as ice bags and cool cloths) should be avoided because they cause shivering, which is heat-generating. Oral fluids and/or ice chips should be encouraged, but the benefit of using parenteral or enteral fluids is highly debated, and it remains undetermined whether hydration improves cognition, especially in individuals using opioids. Oral care with soft applicators should be offered frequently by the family caregiver; in addition to promoting the patient’s comfort, this allows the caregiver to participate in the loved one’s care. A salt-and-soda solution can be used instead of mouthwash. A solution can be made by boiling 1 quart of water and adding 1 teaspoon of salt and 1 teaspoon of baking soda. Chill the solution and use several times a day, as desired. Discard any unused solution after 1 week. Vaseline or other lubricants should be placed on the patient’s lips to prevent dryness and cracking. Special attention to skin is essential, especially to skinfolds; clothing and linens should be changed frequently. Aquaphor, Eucerin, aloe vera, or Vaseline Intensive Care can be applied to maintain skin integrity. Lymphedema patients using a Jobst and Sigvarus compression garment should be instructed to avoid products that contain petroleum because they break down the rubber in the garment. Avoid skin products that contain alcohol because they may actually increase dryness and cause chemical irritation.

A bowel history should be obtained and a laxative or suppository given if constipation is present. An enema or disimpaction may be required. Corticosteroids are effective as antipyretics and can reduce inflammation and pain but are potentially dangerous insofar as immune function is hampered and an infectious process may be masked. The risk-benefit ratio with respect to goals of care must always be considered. In a palliative care setting, neuroleptic agents can be used for centrally mediated fevers. Chlorpromazine (Thorazine) has been used primarily in this setting, probably because among the neuroleptics it is most likely to cause vasodilatation.

Palliative radiation may be needed if the fever is tumor-related, as indicated by the tumor type and general condition of the patient.

CASExSTUDY

Mr. D, a Patient with Fever

Mr. D was an 80-year-old retired pediatrician with a recent history of fever of unknown origin, leukocytosis, elevated erythrocyte sedimentation rate (ESR), anemia, and myalgias. The patient had been in good health until his return from Mexico 2 months earlier, when he developed chills, myalgias, nonproductive cough, and fevers. Antibiotics were prescribed when a chest x-ray showed a left lower-lobe infiltrate. Myalgias continued, especially in the triceps muscles and shoulder girdle muscles. The myalgias were partially relieved by antiinflammatory agents, such as celecoxib (Celebrex), may in certain instances be preferred in this setting.

Cooling measures, such as a tepid cloth to the patient’s forehead, may be comforting; otherwise, cooling measures (such as ice bags and cool cloths) should be avoided because they cause shivering, which is heat-generating. Oral fluids and/or ice chips should be encouraged, but the benefit of using parenteral or enteral fluids is highly debated, and it remains undetermined whether hydration improves cognition, especially in individuals using opioids. Oral care with soft applicators should be offered frequently by the family caregiver; in addition to promoting the patient’s comfort, this allows the caregiver to participate in the loved one’s care. A salt-and-soda solution can be used instead of mouthwash. A solution can be made by boiling 1 quart of water and adding 1 teaspoon of salt and 1 teaspoon of baking soda. Chill the solution and use several times a day, as desired. Discard any unused solution after 1 week. Vaseline or other lubricants should be placed on the patient’s lips to prevent dryness and cracking. Special attention to skin is essential, especially to skinfolds; clothing and linens should be changed frequently. Aquaphor, Eucerin, aloe vera, or Vaseline Intensive Care can be applied to maintain skin integrity. Lymphedema patients using a Jobst and Sigvarus compression garment should be instructed to avoid products that contain petroleum because they break down the rubber in the garment. Avoid skin products that contain alcohol because they may actually increase dryness and cause chemical irritation.

A bowel history should be obtained and a laxative or suppository given if constipation is present. An enema or disimpaction may be required. Corticosteroids are effective as antipyretics and can reduce inflammation and pain but are potentially dangerous insofar as immune function is hampered and an infectious process may be masked. The risk-benefit ratio with respect to goals of care must always be considered. In a palliative care setting, neuroleptic agents can be used for centrally mediated fevers. Chlorpromazine (Thorazine) has been used primarily in this setting, probably because among the neuroleptics it is most likely to cause vasodilatation.
in 1988, and prostate cancer without evidence of metastatic disease. There was no history of rheumatic fever or heart murmur.

Clinical evaluation revealed the patient as an alert, oriented man with intact cognitive functions. Funduscopic examination was impeded by cataract formation, but no Roth spots or areas of hemorrhage were visible. There was slight focal tenderness of the proximal superficial temporal artery, barely notable on the right and mild on the left. There was no nodularity or induration along the course of either of these arteries. Carotid bruits were absent and extracranial artery pulsations were normal. There was no nuchal rigidity. Motor examination was normal for age, without muscle masses or tenderness, except in the calves. He was, however, unable to rise from a chair without the use of his arms and was unsteady on his feet. Gait was wide-based and waddling, with some unsteadiness. Sensation was intact to all modalities, though Romberg's sign was positive for postural imbalance and tandem gait was slightly abnormal. Radial pulses were equal, and pedal pulses were present bilaterally. No cutaneous stigmata of infection or vasculitis was appreciated. Heart sounds were normal, without murmur. There was no hepatomegaly or abdominal tenderness. Areas of bone tenderness were absent.

The impressions were (1) fever of unknown origin, and (2) rule out temporal arteritis.

The diagnostic data were as follows: lumbar puncture was negative, carotid ultrasound showed moderate amount of plaque formation in both common carotid arteries with no significant stenosis, and temporal artery biopsy showed giant cell arteritis.

The patient was treated with prednisone 20 mg tid, with regular monitoring of ESR.

The patient enjoyed complete relief of fevers, night sweats, and myalgias. He was encouraged to exercise, and bone-density studies and blood-sugar levels were monitored during the time he was on prednisone. His ESR returned to normal, and prednisone was gradually tapered.

SWEATS

The sweat glands of the skin, the piloerector muscles, and the vascular skin blood vessels are controlled, at least in part, by the sympathetic nervous system and are intimately involved in temperature regulation. Vasodilatation and sweating allow for evaporative heat loss to lower body temperature in a hot environment, with fevers, or during exercise. Approximately 5% of cancer patients experience sweating as a direct result of malignant disease.96–98

Pathophysiology

The hypothalamus interprets signals from the central and peripheral thermoreceptors. There are two types of thermosensitive neurons, warm-sensitive and cold-sensitive, both of which are located in the preoptic anterior hypothalamus. The more abundant warm-sensitive neurons respond to a rise in temperature in the periphery, whereas the cold-sensitive neurons are triggered by a decrease in body temperature in the periphery.1 Body temperature is read at various thermoreceptors in the skin, spinal cord, and brain stem. Hypercapnia, plasma osmolality, intravascular blood volume changes, and dehydration can affect body temperature and set-point.1

The autonomic nervous system both transmits the thermoregulatory adjustments to the CNS and has a measure of thermoregulatory control independent of the CNS. Postganglionic sympathetic axons innervate sweat glands, blood vessels, and piloerector muscles. Through adjustments in adrenergic vasoconstrictor nerve fibers, cutaneous blood flow is increased or decreased depending on the need to dissipate or conserve heat. Cholinergic fibers innervate the eccrine glands. Thermal sweating occurs when the hypothalamic set-point is exceeded. Signals are transmitted from the hypothalamus by the autonomic nervous system to the effector sweat glands and cutaneous vasculature. Generalized diaphoresis ensues, which lowers body temperature. Emotional sweating is controlled primarily by the limbic system rather than the hypothalamus, and may affect areas of the body differently. Whereas sweating may be either depressed or increased over the trunk and proximal limbs, sweating always increases in the palms of the hands and soles of the feet. Under given circumstances, the quantity of sweating in response either to temperature elevation or emotion is often dependent on age, gender, exercise, hydration, ambient temperature, and sweat gland blood flow. Disorders of sweating include hyperhidrosis (excessive sweating), anhidrosis (absent or decreased sweating), and gustatory sweating (primarily of the face, associated with diabetes). Each of these disorders can arise from dysfunction of either the neural innervation or the sweat glands themselves or both.

Etiology

Anhydrotic ectodermal hypoplasia is an inherited condition in which heat loss through perspiration may be inadequate to lower body temperature. Other cooling methods must be used for thermoregulation (e.g., submersion in cool water, exposure to cool ambient temperatures, cool cloths) to lower temperature.

Hyperhidrosis may be a compensatory mechanism for anhidrosis of other body areas. Thermoregulatory sweat testing can be conducted to assess the peripheral and central sympathetic pathways. Reduced or absent sweating patterns can be identified and the pathology identified as either pre- or postganglionic abnormalities or abnormalities of the sweat glands. Abnormalities of sweating, either excessively dry or wet skin, accompanied by trophic skin changes and thin shiny skin are signs of a peripheral neuropathic disorder. When seen in the setting of limb pain, they typically indicate that the pain is arising, at least in part, on a neuropathic basis.

Generalized hyperhidrosis can occur with various endocrine disorders, such as estrogen deficiency due to menopause.
(related either to the climacteric medical treatment), hyperthyroidism, or hypoglycemia, as well as with various neuroendocrine tumors, such as carcinoid and pheochromocytoma. Hyperhidrosis may also be a sign of chronic infection, such as tuberculosis, or of inflammatory illnesses (e.g., lupus, vasculitis, regional enteritis) even in the absence of fevers. Various malignancies, most notably lymphomas, cause drenching sweats, especially at night. Such night sweats may be an early sign of tumor recurrence. Hyperhidrosis may announce many abstinence syndromes, such as from barbiturates, opioids, or ethanol.1 With opioids, both agonists, such as morphine and methadone, and mixed agonists–antagonists, such as butorphanol and pentazocine, have been associated with excessive sweating, probably due to cutaneous vasodilatation. An opioid rotation may be beneficial in reducing this symptom.1

It is important to evaluate all reported regional disturbances of sweating. Patients with an area of anhidrosis (e.g., related to a Pancoast tumor as a component of Horner’s syndrome) may not notice a decrease in sweating on the affected area but, instead, report hyperhidrosis on the unaffected side.

Nocturnal hyperhidrosis, or night sweats, can be associated with decreased estrogen production such as from menopause, other endocrine disorders, and malignancies. Hormonal therapy for breast and prostate cancers is often associated with troublesome hot flashes, which interfere with sleep patterns. Seventy-five percent of men receiving hormonal therapy experience hot flashes, although the symptom is often overlooked.

Clinical Evaluation/Treatment Options for Hot Flashes

Hot flashes occur as a result of estrogen depletion related to surgery, adjuvant chemotherapy, and hormonal therapy (such as tamoxifen, leuprolide [Lupron], and flutamide [Eulexin]). In the United States, estrogen replacement therapy (ERT) generally is not given to women with a history of breast cancer. Some women are predisposed not only to hot flashes but also to other problems associated with estrogen deficiency, such as osteoporosis and heart disease. In the nonhormonal treatment of hot flashes, such agents as ergotamine tartrate plus phenobarbital (Bellergal), methylprednisolone, and clonidine have been tried, but often with limited success. Other purported remedies include moderate doses of vitamin E, certain antidepressant agents such as paroxetine (Paxil), venlafaxine Hcl (Effexor),101 and anticholinergic agents such as oxybutynin chloride (Ditropan).102 Oxybutynin is an antispasmodic, anticholinergic agent indicated for the treatment of urge incontinence and bladder hyperactivity disorders; it often effectively reduces sweating. It is now available in a sustained-release form, which minimizes the side effects of sleepiness and dry mouth.

Patients living in hot climates must be cautioned against overactivity in the heat because diminished sweating can lead to heat stroke when taking anticholinergic agents. Adequate hydration is important to avoid confusion and hyperthermia. In clinical practice, propranolol hydrochloride (Inderal) has been found to decrease the sympathetic symptoms of hot flashes and night sweats in a variety of illnesses, such as Parkinson’s disease. Thalidomide has been reported to decrease TNF-α production and sweating in patients with tuberculosis, leprosy, rheumatoid arthritis, graft versus host disease, and mesothelioma (where TNF-α levels were elevated).96 There are numerous references in the professional and lay literature regarding use of evening primrose oil and phytoestrogens for menopausal symptoms. Phytoestrogens are found in more than 300 plants (cousmestans: bean sprouts, red clover, and sunflower seeds; lignans: rye wheat, sesame seeds, linseed). Constituent isoflavones are reportedly similar in efficacy to endogenous estrogen at minimizing the symptoms of menopause (hot flashes) and premenstrual syndrome. A recent study evaluating soy phytoestrogens for treatment of hot flashes in breast cancer survivors concluded the soy product did not alleviate hot flashes.99 Black cohosh (Cimicifuga racemosa) is a perennial herb that has emerged as a treatment for hot flashes, but there is no good evidence from controlled trials to support its use.102,103

Mrs. M, a Patient with Hot Flashes

Mrs. M is a 60-year-old woman with a prior history of oophorectomy, who was diagnosed in 1994 with breast cancer. Treatment included a lumpectomy, followed by a segmental resection with axillary node dissection and external radiation therapy. Since her diagnosis, she has taken tamoxifen 10 mg twice a day as a prophylactic measure. Hot flashes were reported as her most distressing symptom. The patient described these episodes as being “drenched,” and they impacted negatively on her quality of life. Sleep was interrupted due to frequent linen changes (two or three per night), and frequent changes of nightwear were required. Past medical history included mitral valve prolapse, type II diabetes, hypertension, hypercholesterolemia, stress incontinence (status post bladder suspension), and oophorectomy.

Mrs. M is a very pleasant, well-developed, well-nourished woman in no distress. Vital signs: T: 35.9°C; P: 95; BP: 162/92; Wt: 84 kg. The physical examination was unremarkable except for the area of the right breast, where a well-healed surgical deficit was present. There was increased density in the tissue of the right breast. There was no erythema and no palpable mass. There was no lymphadenopathy in the supraclavicular region or axillae. There was no nipple discharge. Diagnostic data included fasting blood sugar of 115. The impression is that the hot flashes are related to tamoxifen use.

The patient was given a prescription for a clonidine TTS 1 patch, to be worn weekly, to block the symptoms of excessive sympathetic outflow that caused her hot flashes and sweats, and to treat her hypertension. The clonidine was tried for 1 month, but after this, the patient discontinued the patch, feeling it was ineffective and reporting symptoms of orthostatic hypotension. Hyosphen (Bellergal), which contains phenobarbital, ergotamine, and belladonna, was prescribed, twice a day.
This agent was tried for several days, and while it had some efficacy, the patient found its sedating properties to be unacceptable. Oxybutynin chloride (Ditropan), an anticholinergic and antispasmodic agent, was prescribed. At the starting dose of 5 mg bid, the patient reported that the frequency and intensity of her hot flashes were considerably reduced and that her urinary urgency was also better controlled.

The patient’s quality of life reportedly improved when she was able to sleep through the night without experiencing the hot flashes or nocturia. She was able to decrease the dose of oxybutynin to 5 mg once a day at bedtime.

**Conclusion**

Pruritus, fever, and sweats are frequently seen in end-of-life care but are still not well managed. New pharmacological therapies have evolved in the palliation of these symptoms, and the physiological processes are better understood. Symptoms of pruritus, fever, and sweats should be assessed and recognized as causing distress to the patient and negatively impacting on the patient’s quality of life. In the palliative care setting, treatment of the underlying disease process may be limited but comfort should be a priority.

**References**

Myoclonus, uncontrolled rhythmic jerking movements, often is due to accumulation of opioid metabolites, particularly in patients with renal dysfunction.

Seizures may arise from central nervous system neoplasms, metabolic dysfunction, medications, stroke and other causes. Aggressive management is indicated to reduce pain and exhaustion.

Spasms, involving uncontrolled movement, rigidity, and hyperreflexia, can impair mobility and cause pain. Palliative care includes pharmacological and nonpharmacological management, along with safety measures.

Myoclonus is frequently seen in palliative care settings, particularly during the final days of life. If left untreated, this neurological disturbance may progress to seizures. Seizures also may occur due to central nervous system (CNS) lesions, metabolic disorders, or medications. A third neurological disturbance, spasticity, involves involuntary movements that may produce discomfort and fatigue. Astute palliative care clinicians can prevent some of these disorders and treat those that cannot be prevented. Patient and family involvement is mandatory since comfort and safety issues are prevalent with all three syndromes.

Myoclonus

Myoclonus consists of sudden, uncontrollable, nonrhythmic jerking, usually of the extremities. Frequently seen in the palliative care setting, myoclonus can be exhausting and can progress to more severe neurological dysfunction, including seizures. Early identification and rapid treatment are critical.

Causes of Myoclonus

In the palliative care setting, myoclonus is most often associated with opioids. The prevalence of opioid-induced myoclonus ranges greatly, from 2.7% to 87%. Nocturnal myoclonus is common and often precedes opioid-induced myoclonus. The precise cause of opioid-induced myoclonus is unknown; however, several mechanisms have been proposed. High doses of opioids result in the accumulation of neuroexcitatory metabolites. The best characterized are morphine-3-glucuronide and hydromorphone-3-glucuronide. Serum and cerebrospinal fluid levels, as well as the ratios of these metabolites, are elevated in patients receiving morphine for cancer and nonmalignant pain. This is particularly true for patients with renal dysfunction. However, clinical evidence of myoclonus does

Key Points

- Myoclonus, uncontrolled rhythmic jerking movements, often is due to accumulation of opioid metabolites, particularly in patients with renal dysfunction.
- Seizures may arise from central nervous system neoplasms, metabolic dysfunction, medications, stroke and other causes. Aggressive management is indicated to reduce pain and exhaustion.
- Spasms, involving uncontrolled movement, rigidity, and hyperreflexia, can impair mobility and cause pain. Palliative care includes pharmacological and nonpharmacological management, along with safety measures.
not consistently correlate with serum levels of morphine-3-glucuronide. Hyperalgesia is particularly associated with these metabolites, although other opioids with no known metabolites have also produced myoclonus. A variety of other metabolites of opioids exist, including morphine-6-glucuronide and hydromorphone-6-glucuronide, but these have been implicated in nausea and vomiting, as well as sedation, rather than myoclonus.

Opioids given in high doses may result in myoclonus. Bruera and Pereira reported the development of acute confusion, restlessness, myoclonus, hallucinations, and hyperalgesia due to an inadvertent administration of 5000-mcg intravenous (IV) fentanyl (the patient had been receiving 1000 mcg/hour subcutaneously). These symptoms were successfully treated with several doses of 0.1 to 0.2 mg of IV naloxone, followed by a continuous IV naloxone infusion of 0.2 mg/hour. The patient did not demonstrate withdrawal symptoms initially, yet began to complain of return of pain after several hours (see Chapter 6 regarding the use of diluted naloxone to reverse adverse effects associated with opioids). Other opioids, including methadone, meperidine, and transdermal fentanyl have been implicated in the development of myoclonus.

Other reported causes of myoclonus include surgery to the brain, placement of an intrathecal catheter, AIDS dementia, hypoxia, chlorambucil, and a paraneoplastic syndrome. This paraneoplastic syndrome is rare, occurring in fewer than 1% of people with cancer. The etiology of the paraneoplastic syndrome can also be viral and is believed to be immunologically mediated. Symptoms of this paraneoplastic (also called opsoclonus-myoclonus) syndrome include myoclonus, opsoclonus, ataxia, and encephalopathic features. Treatment of the underlying tumor or infection and immunosuppression are possible treatments.

Assessment

An accurate history from the patient and family is essential. An analogy to help patients describe the symptoms is to compare the jerking to the feeling that often happens when one is close to falling asleep (a common condition called nocturnal myoclonus). The difference is that myoclonus is usually continuous. Physical exam will reveal jerking of the extremities, which is uncontrolled by movement or other activities. Jerking can be induced by single or repeated tapping of a muscle group.

Treatment

Opioid rotation is the primary treatment of myoclonus, particularly if the patient is receiving higher doses of an opioid and has renal dysfunction. There is great variation in individual response to opioids, thus, different agents may have a greater likelihood of producing myoclonus or other adverse effects. Presently, there are no tests that predict individual response, and trials are the only strategy for determining effectiveness as well as adverse effects. In addition, cross-tolerance is not complete, and thus, lower equianalgesic doses of an alternate opioid may provide analgesia. Methadone has been successfully used as an alternative agent, although other opioids may be easier to titrate, and methadone also has been reported to cause myoclonus. Strategies, such as adding adjuvant analgesics, that reduce the necessary amount of opioid could reduce or eliminate myoclonus.

Little research is available regarding agents used to reduce myoclonic jerking. Benzodiazepines, including clonazepam, diazepam, and midazolam, have been recommended. The antispasmodic baclofen has been used to treat myoclonus due to intraspinal opioid administration. Dantrolene has been used, yet it produces significant muscle weakness and hepatotoxicity.

Patient and Family Education

Safety measures are essential, as are interventions designed to reduce fatigue during myoclonus. Use padding around bed rails and assistive devices if the patient is ambulatory. Provide a calm, relaxing environment. Pain assessment is critical as opioids are rotated since equianalgesic conversions are approximations and wide variability exists. Therefore, patients and family members are encouraged to track pain intensity as opioids are titrated to provide optimal relief.

Seizures

Of the many neurological disorders that occur in advanced disease, seizures are the most frightening. This fear exists for the patient and for their caregivers. Furthermore, seizures can be exhausting for the patient, eliminating the few energy reserves that might be better spent on quality activities. Therefore, seizures must be prevented whenever possible. When prevention is not feasible, all attempts should be made to limit the extent of the seizure and ensure safety measures to prevent trauma during these episodes.

Seizures occur when a large number of neurons discharge abnormally. This abnormal discharge produces involuntary paroxysmal behavioral changes. There are two types of seizure, including primary (also called generalized) and focal (also called partial). Primary seizures involve large parts of the brain and include both grand mal and petit mal types. Focal seizures are isolated to specific regions of the brain, and symptoms reflect the area of disturbance. For example, Jacksonian motor seizures result from abnormal discharge in the motor cortex. These patients may have involuntary twitching of muscle groups, usually on the contralateral side of the body. If the tumor is located in the left motor cortex (anterior to the central sulcus), the activity is seen on the right side of the body. Often, activity begins in one area and spreads throughout that side of the body as abnormal discharge spreads to nearby cortical neurons. Patients generally remain conscious, unless the abnormal cortical discharge spreads to the opposite
hemisphere. In the palliative care setting, there are many potential causes of seizure activity.

Causes of Seizures

Careful consideration of the many causes of seizure activity must be included in the assessment of patients at the end of life, whether the patient has demonstrated seizure activity or not. This allows prevention whenever possible. Primary or metastatic neoplasms to the brain are common causes of seizures in palliative care, as are preexisting seizure disorders. Medications, including phenothiazines, butyrophenones, and tricyclic antidepressants, can lower the seizure threshold. Other medication-related causes of seizures include metabolites (e.g., normeperidine), preservatives within these compounds (e.g., sodium bisulfite), or the abrupt discontinuation of certain drugs (e.g., benzodiazepines). Additional causes of seizures at the end of life include metabolic disorders, infection, HIV, stroke, hemorrhage, oxygen deprivation, and some rare paraneoplastic syndromes (Table 18–1).

Primary or Metastatic Brain Tumors. Brain tumors can result in either primary generalized or focal seizures. Seizures occur in approximately 25% of those with brain metastases. Patients with malignancies known to metastasize to the brain, such as breast, lung, hypernephroma, and melanoma, should be considered at risk for seizures. Leukemias and lymphomas are also known to produce infiltrates in the brain. Multiple metastases or brain and leptomeningeal disease are more commonly associated with seizures. The tumor location, size, and histology dictate whether seizures may result and the resulting symptoms associated with the seizure.

Medications. Medications can lead to seizures in the palliative care setting through several mechanisms. Medications such as the phenothiazines, butyrophenones, and tricyclic antidepressants can place patients at risk by lowering the seizure threshold. These agents should be used cautiously in patients with intracranial tumors or infection. There are reports of patients developing seizures due to fluoroquinolones, including ofloxacin and ifosfamide (more likely if serum creatinine is elevated and the patient has had prior treatment with cisplatin), as well as cephalosporins and monobactams. In very high doses, any opioid can lead to seizures. Several opioids are associated with much higher risk due to their metabolites that cause seizures. Meperidine is converted to normeperidine during metabolism. Individuals with renal dysfunction cannot excrete normeperidine efficiently; the metabolite then accumulates in the bloodstream and leads to seizures. Therefore, the clinical practice guidelines developed by the American Pain Society for cancer pain strongly discourage the use of meperidine in any patient, a practice long known to those in palliative care. These guidelines also discourage the use of propoxyphene (the weak opioid in Darvon) in persons with cancer due to the metabolite norpropoxyphene.

More recently, morphine and hydromorphone have been found to be metabolized by glucuronidation to morphine-3-glucuronide or hydromorphone-3-glucuronide, respectively. These metabolites may produce hyperalgesia (elevated pain intensity), myoclonus (see previous section), and seizure in patients unable to excrete these efficiently. Clinically, patients respond acceptably to the opioid for the first day or two, then develop symptoms after the metabolite has accumulated. Alternately, the patient may have obtained good relief in the absence of opioid neurotoxicity, until renal status diminishes, with concomitant difficulties in clearing the metabolite. Another opioid, tramadol, has been associated with seizure risk, especially when taken with other drugs that lower the seizure threshold.

Compounds added to medications to preserve the drug or prevent its breakdown (such as sodium bisulfite) are normally present in extremely small amounts. However, when high doses of a drug, usually opioids, are needed to treat severe pain, the concomitant dose of these additives increases. In this setting, there have been rare reports of seizures. Using preservative-free solutions when administering high doses of any agent may prevent this activity. Hagen and Swanson report a syndrome of opioid hyperexcitability that progressed to seizures in five patients with high-dose infusions. Parenteral midazolam infusion was used to treat the seizures, the patients were rotated to alternative opioids (including levorphanol and methadone), and aggressive supportive care was provided during the episodes.

Rapid cessation of various drugs can lead to seizure activity in the palliative care setting. Often, this occurs when staff are unaware that a patient uses certain medications and, as a result, these drugs are not provided when patients are hospitalized or unable to independently dispense their own drugs. Benzodiazepines, barbiturates, and baclofen are the most common drugs associated with seizures during abstinence. This also can occur when the patient abuses these compounds or alcohol and the staff or family is unaware. Alcohol abuse often is underrecognized in the palliative care setting.

Other Causes of Seizures in Palliative Care. Infection within the brain, as may be seen in persons with human immunodeficiency virus (HIV) or acquired immunodeficiency syndrome (AIDS), can lead to seizure activity. The syndrome of inappropriate antidiuretic hormone, associated with lung cancer and other malignancies, can result in increased water and sodium content within the cells. The resultant swelling of neuronal cells within the brain causes increased intracranial pressure (ICP). Anoxia deprives the brain of needed nutrients, resulting in an inability to drive sodium out of neuronal tissue. Water follows into the cells, creating increased ICP. Hyponatremia (<130 mEq/L) can also lead to mental status changes and seizures, especially when of rapid onset.

Assessment

Conduct a thorough history from the patient and caregiver to ascertain any symptoms existing with the onset of the seizure, the specific type of seizure activity, and whether there was any aura immediately before the seizure. Headache, nausea, and projectile vomiting are associated with increased ICP and can occur immediately before seizure activity. The family may relate a staring-type behavior, where the patient does not respond to stimuli for a brief moment.

The past medical history might reveal a seizure disorder. Review all drugs recently added to the plan of care for agents that might lower the seizure threshold or produce metabolites. Question whether the patient recently discontinued a drug, including recreational drugs. If the patient is currently taking anticonvulsants or corticosteroids for seizures and increased ICP, determine if there could be reasons that the drugs were not ingested or absorbed. These might include compliance issues or nausea and vomiting.

Often, the clinician may not witness the seizure and must rely on the observation and memory of family members and caregivers. Assist family members in differentiating between seizures and myoclonus (see previous section) or altered level of consciousness due to other etiologies. A thorough examination is indicated, with attention to bruises and other signs of trauma. If these occur, additional teaching for family and caregivers regarding safety measures is warranted.

Measuring serum levels of anticonvulsants may be indicated to insure that the drug is adequately absorbed. Dose adjustments may be done empirically based on the patient’s condition. Electroencephalography may be used to identify the site of abnormal discharge. Brain lesions may be scanned using computed tomography (CT) or magnetic resonance imaging (MRI). These tests should only be considered if they will provide information that will guide therapy and if they are consistent with the patient’s and family’s goals of care.

Treatment

Anticonvulsants are used when patients have demonstrated seizures (Table 18–2). The prophylactic use of anticonvulsants in patients who have not had a seizure is controversial. Only in the case of brain metastases from melanoma has prophylactic anticonvulsant therapy demonstrated benefit. The potential benefits must be weighed against the side effects associated with these agents.

The most common anticonvulsants used in the United States to prevent seizures are phenytoin, carbamazepine, valproate, and phenobarbital (see Table 18–2). Newer anticonvulsants, such as gabapentin, vigabatrin, and lamotrigine, have not been extensively studied in the palliative care setting. Agents used during a seizure include diazepam, lorazepam, midazolam, phencytoin, and phenobarbital (Table 18–3).

A particular challenge in palliative care is the administration of these drugs when the patient is unable to take oral medications. The intramuscular route can be used for some (diazepam and phenobarbital), but since this route is painful and absorption is unpredictable, its use should be reserved for situations when no other access is practical or possible.

Phenobarbital is available in a solution for parenteral delivery, and pentobarbital (used more commonly in Canada and Europe) is available in rectal formulations. Intravenous phencytoin can lead to the purple-glove syndrome, a potentially serious local complication including edema, discoloration, and pain distal to the injection site. Fosphenytoin, although more expensive, has an advantage in palliative care because it can be given subcutaneously (by either intermittent injection or infusion) for prevention or treatment of seizures. Dosing is based on phenytoin equivalents, generally 5- to 10-mg phenytoin equivalent/kg. Little research has compared the efficacy of these agents, particularly in the palliative care setting. The choice of agent is often based on the availability of the drug, comfort level of the practitioner, ability to use nonoral routes, and other factors. Because most medications are administered by nonprofessional caregivers in the home, often elderly spouses of aged patients, it is best to keep the drug regimen simple.

Many patients with seizure disorders will also be taking dexamethasone. Dexamethasone is technically not an anticonvulsant, yet this compound is critical when intracranial lesions that might increase ICP are present. Although most texts suggest four-times-a-day (qid) dosing, the long half-life of dexamethasone allows daily dosing with adequate serum levels maintained throughout the 24-hour period. Of additional concern is the interaction between phenytoin and dexamethasone. Phenytoin can decrease the bioavailability of dexamethasone by as much as 20%. Additionally, dexamethasone inhibits the metabolism of phenytoin, reducing the anticonvulsant effect of this drug. Thus, extreme care must be exercised when adding or titrating either drug when using combinations. Phenytoin can alter plasma levels of several drugs (Table 18–4). In the palliative care setting, if a patient decides to stop all corticosteroids, the professional must evaluate the likelihood of developing seizures. Prophylactic therapy must be considered.

SQ = subcutaneous; IV = intravenous.
Status epilepticus is a seizure that persists longer than 5 minutes or repeated seizures without a return to consciousness between each episode. This is considered a neurological emergency. Clear the airway, ensure adequate perfusion, give glucose (usually 50 mL of a 50% solution), evaluate electrolytes, and administer IV benzodiazepine (such as diazepam or lorazepam), followed by a loading dose of IV phenytoin. The Veterans Administration Cooperative Trial of Status Epilepticus revealed response rates during first-line treatment as follows: lorazepam 64.9%, phenobarbital 58.2%, diazepam plus phenytoin 55.8%, and phenytoin alone 43.6%. These results suggest that lorazepam should be the first drug of choice. If the seizure is not relieved in 5 to 7 minutes, add phenytoin or fosphenytoin. If recurrent, continuous infusion of phenobarbital or diazepam is indicated. In extreme cases, barbiturate anesthesia, neuromuscular blockade, and propofol may be indicated.

### Drugs that may decrease phenytoin serum levels
- Carbamazepine, chronic alcohol abuse, reserpine, sucralfate, antacids with calcium (should not be taken with phenytoin but at a different time)

### Drugs that may have reduced efficacy due to phenytoin
- Corticosteroids (including dexamethasone), coumarin anticoagulants, digitoxin, doxycycline, estrogens, furosemide, oral contraceptives, quinidine, rifampin, theophylline, vitamin D

**Patient and Family Education**

Witnessing a seizure can be extremely frightening for family members and caregivers. Preparation is critical. Explain that restraining the patient or attempting to place objects in the mouth can lead to significant harm. Educate family members and caregivers. Preparation is critical. Explain that

To help recovery after a seizure, the patient may benefit from reduced stimulation. Lower the lights, reduce the sound of televisions or radios, and speak softly and reassuringly. Assess for pain and treat accordingly. Relaxation exercises also may be helpful. Often, patients will sleep for several hours after the seizure.

### Case Study

**A 31-Year-Old Man with Intractable Nausea and Vomiting**

A 31-year-old man was admitted to the oncology unit with intractable nausea and vomiting, presumably due to appendiceal cancer with omental and peritoneal metastases. He previously had been treated with a right hemicolecction and diverting ileostomy, systemic chemotherapy, and a venting gastrostomy tube with total parenteral nutrition when obstruction occurred. Abdominal pain was treated with IV hydromorphone 26 mg/hour, with 26 mg every 15 minutes as needed. Several hours after admission to the unit he developed myoclonus, hyperreflexia, agitation, delirium, and eventually, tonic–clonic seizures. Evaluation revealed acute obstructive renal failure (BUN 37 mg/dL, creatinine 4.2 mg/dL) secondary to diffuse carcinomatosis.

Because the opioid metabolite hydromorphone-3-glucuronide was suspected as the likely cause of these neurological disturbances, the hydromorphone dose was reduced by 50% and the bolus dose was discontinued. Phenytoin (Dilantin) 1 gram followed by a 200-mg IV bolus every 12 hours did not stop the seizures; neither did valproate sodium (Depakon) 500-mg IV infusion every 12 hours, chlorpromazine (Thorazine) 25-mg slow IV push every 6 hours, lorazepam 2-mg IV every 2 hours, or diazepam 5 mg every 5 to 10 minutes. Despite these efforts, the generalized tonic–clonic movements increased in intensity and frequency (every 8 to 10 minutes) to status epilepticus. The patient was disoriented, yet remained arousable,
able to follow simple commands, and appeared to be in pain during these seizures.

Because the family’s goals were to keep the patient comfortable, a midazolam infusion was begun at 1 mg/hour and rapidly titrated upward to 96 mg/hour, without change in frequency or intensity of seizures unfortunately. A nationwide shortage of phenobarbital prompted the use of pentobarbital 1 gram over 1 hour, followed by a 40-mg/hour infusion, with no change in seizure activity. A propofol (Diprivan) infusion was started, with a bolus of 80 mg given over 1 hour, and an infusion of 160 mg/hour. The patient experienced three more seizures, and then they stopped; he died approximately 6 hours later in apparent comfort.65

Spasticity

Spasticity is a movement disorder that results in a partial or complete loss of supraspinal control of spinal cord function. Patients may exhibit involuntary movement, abnormal posture, rigidity, and exaggerated reflexes. Spasticity may interfere with all aspects of life by limiting mobility, disturbing sleep, and causing pain.66 Spasticity is often associated with advanced multiple sclerosis (MS), spinal cord trauma, tumors of the spinal cord, stroke menigitis, and other infections.67–69 In a study of 2104 patients with nontraumatic spasticity seen in a regional neuroscience center in the United Kingdom, 17.8% had MS, 16.4% had neoplasm, and 4.1% had motor neuron disease.60

Assessment

Patients will describe a gradual onset of loss of muscle tone, followed by resistance and jerking when muscles are flexed. A recent history of urinary tract infection, decubitus ulcer, constipation, or pain may immediately predate the onset, or increased episodes, of spasticity.

Physical exam will yield resistance and spasticity when doing passive limb movement. The faster the passive movement, the more pronounced the effect. Reflexes may be hyperactive, particularly in the affected area. Bruises are common as patients inadvertently and uncontrollably move their limbs, resulting in trauma.

Management

The standard therapies for reducing spasticity include oral baclofen, a gamma-aminobutyric acid-B agonist. Baclofen is generally started with lower doses, 5 to 10 mg/day, and titrated upward gradually, using three- or four-times-a-day dosing. Although effective for some patients, higher doses are often necessary, frequently resulting in cognitive changes and dizziness. For this reason, intrathecal baclofen has been administered with good results.51 Those in palliative care must weigh the benefits of intrathecal baclofen therapy given the patient’s prognosis, the availability of skilled clinicians to administer the therapy, cost, and other factors.

Muscle relaxants, such as dantrolene 50 to 100 mg/day, diminish the force of the contraction.67 Start at 25 mg daily and increase by 25-mg increments in divided doses every 4 to 7 days. The contents can be mixed with liquids if the patient is unable to swallow capsules. Although this reduces spasticity, significant impairment in muscle strength can occur. Therefore, dantrolene is not recommended in ambulatory patients. Furthermore, dantrolene can cause hepatotoxicity. Marijuana, and its active ingredient delta-9-tetrahydrocannabinol (THC), has been described by patients as useful in the relief of spinal cord spasticity.52 Although not approved for this purpose, there is general agreement within the medical community that the treatment of spasticity is a legitimate use of THC. However, despite data supporting its safety and the availability of a commercially prepared product (Marinol), some patients, family members, and health care professionals continue to feel uneasy regarding the use of this compound.

Patient and Family Education

Patients and their caregivers should be educated about factors that may worsen spasticity, including constipation, urinary tract infection, pressure ulcers, fatigue, and psychosocial concerns. Strategies to prevent and relieve these conditions should be clearly communicated, and early communication regarding their onset should be encouraged. When spasticity occurs, the patient and family members must understand the rationale for drug therapy. Nonpharmacological therapy also may be helpful. Family members may be encouraged to gently massage the affected extremities, although this may produce increased spasticity in some patients. Repositioning, heat, and range-of-motion exercises have been described by patients as being helpful. As with other neurological disorders, safety measures are imperative. Padding wheelchairs, bed rails, and any other furniture that might come in contact with spastic extremities will reduce trauma.

Conclusion

Neurological disorders, including myoclonus, seizures, and spasticity, create fear, reduce energy levels, increase pain, and can complicate the course of a patient’s illness. The goal in palliative care is prevention whenever possible. When not possible, early diagnosis and treatment are critical. Knowledge of pharmacotherapy is essential, including agents that might precipitate these disorders, drugs that are used to treat these syndromes, and drug interactions that might occur in the palliative care setting. As with all aspects of palliative care, the patient and family are the center of care. Nurses skilled in palliative care can empower them through education and support. The interdisciplinary approach exemplified by palliative care is key.

Key Points
- The psychosocial issues in persons facing life-threatening illness are influenced by individual, sociocultural, medical, and family factors.
- Emotional turmoil may occur at times of transition in the disease course.
- Anxiety and depression are common symptoms in individuals facing chronic or life-threatening illness but should not be regarded as an inevitable consequence of advanced disease.
- These symptoms warrant evaluation and appropriate use of pharmacological and psychosocial interventions.

Case Study
Mrs. Brady, a Patient with Depression

Mrs. Brady, a 42-year-old housewife and mother of two small children, was referred for consultation following segmental resection for probable stage IV breast cancer, with 15 positive nodes and one small area of questionable bone metastasis noted on her left hip. On being told that she required chemotherapy, she refused, saying “It is hopeless—I can’t do what I want to. Yesterday my grandchild fell on a broom. I felt so bad I couldn’t run to save her. I feel so inadequate in this world. This dependency is driving me crazy.”

Anxiety and Depression

I am not complete because my body does not function now. Before I was almost a normal person. Everything functioned even though I had pain for many years. I’m impotent now—I can’t do what I want to. Yesterday my grandchild fell on a broom. I felt so bad I couldn’t run to save her. I feel so inadequate in this world. This dependency is driving me crazy.—A patient

This chapter provides information regarding the assessment and treatment of anxiety and depression among individuals who are faced with chronic or life-threatening illness and delineates psychosocial interventions that are effective at minimizing these troubling symptoms. Practical guidelines regarding patient management and identifying patients who may require formal psychiatric consultation are offered.
now had anger toward her physician that her life was needlessly compromised by late diagnosis of something she had attempted to avoid for so long. The anger and hopelessness together were overwhelming, and she could not focus on anything else.

Changes in Health Care that have Accentuated Psychiatric Symptoms

Changes in health care delivery and rapid scientific gains are simultaneously increasing the number of individuals receiving or in need of palliative care at any given time, the longevity and course of chronic diseases, and the prevalence and intensity of the psychological symptoms that accompany them.\(^3\)\(^4\) Furthermore, psychological distress is experienced within an increasingly complex, fragmented, and impersonal health care system that intensifies symptoms. Despite these realities, psychological symptoms receive minimal attention, and health care providers often lack the education and support regarding assessment, treatment, and referral of these common problems.

Advances in science and technology have moved the crisis of a life-threatening medical diagnosis to the prediagnostic period, extending life expectancy and the number of treatment courses delivered over a lifetime. Individuals are being diagnosed earlier and living longer, with increasing opportunities to experience simultaneous, interrelated psychosocial and medical comorbidity. The human genome project has theoretically and, in some cases, practically moved the psychosocial implications of chronic disease into the prediagnostic period. Concurrent treatment discoveries have increased quantity of life, albeit with ill-defined consequences to quality of life.\(^3\)\(^5\) For example, an individual who learns of an inherited predisposition to cancer at age 25 is diagnosed at age 50, and receives intermittent treatment until death at age 79 incurs innumerable insults to her mental health and psychological well-being.

Soaring medical costs, managed-care arrangements, and the stigma associated with mental illness have simultaneously placed a low priority on the recognition and treatment of psychosocial distress within our health care system. There is abundant documentation that psychiatric morbidity, particularly depression, and anxiety enhance vulnerability and create formidable barriers to integrated health care.\(^3\) Psychological factors have long been implicated as barriers to disease prevention, early diagnosis, and comprehensive treatment.\(^1\)\(^3\) Lack of assessment and treatment of the common psychiatric sequelae to chronic disease have been linked to such problems as treatment-resistant depression and anxiety, family dysfunction, lack of compliance with prevention and treatment recommendations, potentiation of physical symptoms, and suicide, to name just a few.\(^1\)\(^2\) These issues create long-term problems that drive up health care expenses and diminish access, quality, and efficiency of care. In health care settings, physical problems assume priority in the growing competition for scarce resources. Clinicians confronted with ambiguous symptoms are likely to interpret them within diagnostic paradigms most consistent to their specialty and theoretical orientation. As a consequence, the psychological symptoms that accompany life-threatening conditions are often interpreted and treated inappropriately, rendering care that is not comprehensive or cost effective.

We are at a critical juncture in the evolution of health care in this country. Systems are being overwhelmed by serious, often preventable, diseases that are not being treated comprehensively after diagnosis. Furthermore, in spite of cutting-edge therapies, a significant number of individuals experience unfavorable outcomes. As budget constraints limit the use of psychiatric specialists, these issues have intensified, and the importance of educating “front line” health providers to recognize and address psychiatric morbidity is clear and compelling. In a health care system focused largely on pathogenesis, cure, and cost, psychological symptoms are all too often unrecognized and untreated in clinical settings, despite their insidious harm to patients, caregivers, and the health professionals who feel ill prepared to manage them. As psychiatric-consultation liaison nurses who work primarily in non-psychiatric settings, the authors have been consistently impressed by the lack of knowledge of nursing and medical staff regarding key signs and symptoms that characterize depression and anxiety in the medically ill. Often, young patients with particularly poor prognoses, who elicit anxiety and sadness from staff, rather than their objectively depressed or anxious counterparts, are referred for psychiatric evaluation. Among depressed and/or anxious patients who are referred for evaluation, the decision to intervene with psychotherapy or pharmacological agents is often based largely on the philosophy, educational background, and past experience of individual clinicians. Often, a diagnosis of clinical anxiety or depression is ruled out if the symptoms seem reactive and appropriate to the situation or are viewed as organic in nature. Patients who exhibit depressive or anxious symptoms not considered severe enough to classify for “psychiatric” status are often not offered psychotherapeutic services, and the natural history of their symptoms is rarely monitored over time. The lack of attention to assessment and treatment of depression and anxiety among the medically ill may lead to ongoing dysphoria, family conflict, noncompliance with treatment, increased length of hospitalization, persistent worry, and suicidal ideation, to name just a few risks. Because depression and anxiety are common among individuals with chronic illness, and particularly because they are often responsive to treatment, recognition of those afflicted is of unquestionable clinical relevance. Patients, family, and professional caregivers need to be informed of the factors that affect psychological adjustment, the wide range of psychological responses that accompany chronic and progressive disease, and the efficacy of various modes of intervention at minimizing psychological distress and thus promoting adaptation.
The Clinical Course of Chronic Illness

Acute stress is a common response to the diagnosis of a life-threatening chronic illness that occurs at transitional points in the disease process (beginning treatment, recurrence, treatment failure, disease progression).7 The response is characterized by shock, disbelief, anxiety, depression, sleep and appetite disturbance, and difficulty performing activities of daily living. Under favorable circumstances, these psychological symptoms should resolve within a short period.7,8 The time period is variable, but the general consensus is that once the crisis has passed and individuals know what to expect in terms of a treatment plan, psychological symptoms diminish.7,9 The stage of disease at the time of diagnosis and its clinical course, including medical treatments, recurrence, and prominent symptoms, impact the psychosocial profiles of individuals. To a large extent, these factors will determine the emotional issues that are most pressing at any given point. Patients who are diagnosed with late-stage disease or have aggressive illnesses with no hope for cure are often most vulnerable to psychological distress, particularly anxiety, depression, family problems, and physical discomfort.

Diagnostic Phase

The period from time of diagnosis through initiation of a treatment plan is characterized by medical evaluation, the development of new relationships with unfamiliar medical personnel, and the need to integrate a barrage of information that, at best, is frightening and confusing. Patients and families experience heightened responsibility, concern, and isolation during this period. They are particularly anxious and fearful when receiving initial information regarding diagnosis and treatment. Consequently, care should be taken by professionals to repeat information over several sessions and to inquire about patients’ and families’ understanding of facts and options. Weissman and colleagues described the first 100 days following a cancer diagnosis as the period of “existential plight.”9 Psychological distress varied according to patient diagnosis. Individuals with lung cancer who had predominantly late-stage disease were more distressed than individuals with early-stage disease, supporting the need for palliative care services directed toward psychological symptoms. During the diagnostic period, patient concerns focus on existential issues of life and death more than on concerns related to health, work, finances, religion, self, or relationships with family and friends. While it is unusual to observe extreme and sustained emotional reactions as the first response to diagnosis, it is important to assess the nature of early reactions because they are often predictive of later adaptation.10,11 Early assessment by clinicians can help to identify individuals at risk for later adjustment problems or psychiatric disorders and are in the greatest need of ongoing psychosocial support.7,12 The initial response to diagnosis may be profoundly influenced by a person’s prior association with a particular disease.13 Those with memories of close relatives with the same illness often demonstrate heightened distress, particularly if the relative died or had negative treatment experiences. During the diagnostic period, patients may search for explanations or causes for their disease and may struggle to give personal meaning to their experience. Since many clinicians are guarded about disclosing information until a firm diagnosis is established, patients may develop highly personal explanations that can be inaccurate and provoke intensely negative emotions. Ongoing involvement and accurate information will minimize uncertainty and the development of maladaptive coping strategies based on erroneous beliefs. While the literature substantiates the devastating emotional impact of a life-threatening chronic illness, it also well documents that many individuals cope effectively. Positive coping strategies, such as taking action and finding favorable characteristics in the situation, have been reported to be effective.14 Contrary to the beliefs of many clinicians, denial also has been found to assist patients in coping effectively,15 unless sustained and used excessively to a point that it interferes with appropriate treatment. Health care practitioners play an important role in monitoring and supporting psychosocial adjustment. With an awareness of the unique meaning the individual associates with the diagnosis, it is vital that practitioners keep patients informed and involved in their care. Even though patients may not be offered hope for cure, assisting them in maintaining comfort and control promotes adaptation and improved quality of life.

Recurrence and Progressive Disease

Development of a recurrence after a disease-free interval can be especially devastating for patients and those close to them. The point of recurrence often signals a shift into a period of disease progression and is clearly a time when palliative care services aimed at alleviating psychological symptoms are indicated. The medical workup is often difficult and anxiety-provoking;16 psychosocial problems experienced at the time of diagnosis frequently resurface, often with greater intensity.17,18 Shock and depression often accompany relapse and require individuals and their families to reevaluate the future. This period is a difficult one, during which patients may also experience pessimism, renewed preoccupation with death and dying, and feelings of helplessness and disenchantment with the medical system. Patients tend to be more guarded and cautious at this time and feel as if they are in limbo.19 Silverfarb and colleagues18 examined emotional distress in a cross-sectional study of 1,46 women with breast cancer at three points in the clinical course (diagnosis, recurrence, stage-of-disease progression). The point of recurrence was found to be the most distressing time, with an increase in depression, anxiety, and suicidal ideation. As a disease progresses, the person often reports an upsetting scenario that includes frequent pain, disability, increased dependence on others, and diminished functional ability, which often potentiates psychological symptoms.19 Investigators studying quality of life in cancer patients have demonstrated a clear relationship between an individual’s perception of quality of life and the presence of discomfort.20 As
uncomfortable symptoms increase, perceived quality of life diminishes. Thus, an important goal in the psychosocial treatment of patients with advanced chronic illness focuses on symptom control.

An issue that repeatedly surfaces among patients, family members, and professional care providers deals with the use of aggressive treatment protocols in the presence of progressive disease. Often, patients and families request to participate in experimental protocols even when there is little likelihood of extending survival. Controversy continues about the efficacy of such therapies and the role health professionals can play in facilitating patients' choices about participating. These issues become even more important because changes in the health care system may limit payment for costly and highly technical treatments, such as bone marrow transplants. It is essential for health care professionals to establish structured dialogue with patients, family members, and care providers regarding treatment goals and expectations. Despite the existence of progressive illness, certain individuals may respond to investigational treatment with increased hope. Efforts to separate and clarify values, thoughts, and emotional reactions of care providers, patients, and families to these delicate issues is important if individualized care with attention to psychological symptoms is to be provided. Use of resources such as psychiatric consultation-liaison nurses, psychiatrists, social workers, and chaplains can be invaluable in assisting patients, family members, and staff to grapple with these issues in a meaningful and productive manner.

**Terminal Disease and Dying**

Once the terminal period has begun, it is usually not the fact of dying but the quality of dying that seems to be the overwhelming issue confronting the patient and family.\(^{21,22}\) Continued palliative care into the terminal stage of cancer relieves physical and psychological symptoms, promotes comfort, and increases well-being. Often, patients and families who have received such services along the illness trajectory will be more open and accepting of palliative efforts in the final stage of life. In addition, it is important that nurses caring for the terminally ill recognize the emotional impact on themselves and attend to self-care. Patients living in the final phase of any advanced chronic illness experience fears and anxiety related to uncertain future events, such as unrelieved pain, separation from loved ones, burden on family, and loss of control. Psychological maladjustment is more likely in persons confronting diminished life span, physical debilitation associated with functional limitation, and/or symptoms associated with toxic therapies for which there are no effective interventions.\(^{19,23}\) Therapeutic interventions should be directed toward increasing patients' sense of control and self-efficacy within the context of functional decline and increased dependence. In addition, if patients so desire, it is often therapeutic to let them know that there is help available to discuss the existential concerns that often accompany terminal illness. Personal values and beliefs, socioeconomic and cultural background, and religious belief systems influence patients' expectations about quality of life and palliative care. Cultural affiliation has a significant influence on perception of pain; for example, the findings of Bates and colleagues\(^{24}\) indicate that the best predictors of pain intensity are ethnic group affiliation and locus of control style. For example, an individual's stoic attitude, which serves to minimize or negate discomfort, may be related to a cultural value learned and reinforced through years of family experiences. Similarly, an individual's highly emotional response to routine events may become exaggerated during the terminal phase of illness and not necessarily signal maladjustment but, rather, a cultural norm. Awareness of the family system's cultural, religious, ethnic, and socioeconomic background is important in the understanding of their beliefs, attitudes, practices, and behaviors related to illness and death. Cultural patterns play a significant role in determining how individuals and families cope with illness and death.\(^{25,26}\) Delirium, depression, suicidal ideation, and severe anxiety are among the most common psychiatric complications encountered in terminally ill cancer patients.\(^{27}\) When severe, these problems require urgent and aggressive assessment and treatment by psychiatric personnel, who can initiate pharmacological and psychotherapeutic treatment strategies. Psychiatric emergencies require the same rapid intervention as distressing physical symptoms and medical crises. In spite of the seemingly overwhelming nature of psychosocial responses along the chronic illness trajectory, most patients do indeed cope effectively. Periods of intense emotions, such as anxiety and depression, are not necessarily the same as maladaptive coping.

**Factors That Affect Psychological Adjustment**

Psychological responses to chronic illness vary widely and are influenced by many individual factors. A review of the literature points to key factors that may impact psychological adjustment and the occurrence and expression of anxiety and depression. Three of the most important factors are previous coping strategies and emotional stability, social support, and symptom distress. In addition, there are common medical conditions, treatments, and substances that may cause or intensify symptoms of anxiety and depression (Table 19–1, Table 19–2).

**Previous Coping Strategies and Emotional Stability**

One of the most important predictors of psychological adjustment to chronic illness is the emotional stability and coping strategies used by the person prior to diagnosis.\(^{28}\) Individuals with a history of poor psychological adjustment and of clinically significant anxiety or depression are at highest risk for emotional decompensation\(^{29}\) and should be monitored closely throughout all phases of treatment. This is particularly true for people with a history of major psychiatric syndromes and/or psychiatric hospitalization.\(^{30}\)

Social Support

Social support consistently has been found to influence a person's psychosocial adjustment to chronic illness. The ability and availability of significant others in dealing with diagnosis and treatment can significantly affect the patient's view of him- or herself and potentially the patient's survival. Individuals diagnosed with all types of life-threatening chronic disorders experience a heightened need for interpersonal support. Individuals who are able to maintain close connections with family and friends during the course of illness are more likely to cope effectively with the disease than those who are not able to maintain such relationships. This is especially true during the palliative care period.

Symptom Distress

The effects of treatment for a variety of chronic diseases as well as the impact of progressive illness can inflict transient and/or permanent physical changes, physical symptom distress, and functional impairments in patients. It is a well-known clinical fact supported by research that excessive psychological distress can exacerbate the side effects of cancer-treatment agents. Conversely, treatment side effects can have a dramatic impact on the psychological profiles of patients. The potential for psychological distress, particularly anxiety and depression, appears to increase in patients with advanced illness, especially when cure is not viable and palliation of symptoms is the issue. In a study that elicited information from oncology nurses regarding psychiatric symptoms present in their patients, almost twice as many patients with metastatic disease were reported to be depressed in contrast to those with localized cancers. Investigators studying quality of life in cancer patients have demonstrated a clear relationship between an individual's perception of quality of life and the presence of discomfort. As uncomfortable symptoms increase, perceived quality of life diminishes and psychiatric symptoms often worsen. The presence of increased physical discomfort combined with a lack of control and predictability regarding the occurrence of symptoms often amplifies anxiety, depression, and organic mental symptoms in patients with advanced disease.

Differentiating Psychiatric Complications from Expected Psychological Responses

Differentiating between symptoms related to a medical illness and symptoms related to an underlying psychiatric disorder is particularly challenging to health care practitioners. Anxiety and depression are normal responses to life events and illness and occur throughout the palliative care trajectory. It is the intensity, duration, and extent to which symptomatology affects functioning that distinguishes an anxiety or depressive disorder from symptoms that individuals generally experience in the progression of an illness. Symptoms following stressful events (employment difficulties, retirement, death of a family member, loss of a job, diagnosis of a medical illness/life-threatening illness) in a person's life are expected to dissipate as an individual copes, with reassurance and validation from family and friends, and adapts to the situation. When responses predominantly include excessive nervousness, worry, and fear, diagnosis of an adjustment disorder with anxiety is applied. If an individual responds with tearfulness and feelings of hopelessness, he or she is characterized as experiencing an adjustment disorder with depressed mood. An adjustment disorder with mixed anxiety and depressed mood is characterized by a combination of both anxiety and depression.

Referrals from primary care providers for psychiatric assistance with psychopharmacological treatment are indicated when symptoms continue, intensify, or disrupt an individual's life beyond a 6-month period, or when symptoms do not respond to conventional reassurance and validation by the primary care provider and support from an individual's social network. Most patients develop transient psychological symptoms that are responsive to support, reassurance, and information about what to expect regarding a disease course and its treatment. There are some individuals, however, who require more aggressive psychotherapeutic intervention, such as pharmacotherapy and ongoing psychotherapy. Following are guidelines to help clinicians identify patients who exhibit behavior that suggests the presence of a psychiatric syndrome.

If the patient's problems become so severe that supportive measures are insufficient to control emotional distress, referral to a psychiatric clinician is indicated. Factors that may predict major psychiatric problems along the chronic illness trajectory include past psychiatric hospitalization; history of significant depression, manic-depressive illness, schizophrenia, organic mental conditions, or personality disorders; lack of social support; inadequate control of physical discomfort; history of or current alcohol and/or drug abuse; and currently prescribed psychotropic medication. The need for psychiatric referral among patients receiving psychotropic medication deserves specific mention because it is often overlooked in clinical practice. Standard therapies used to treat major chronic diseases, such as surgery and chemotherapy, and/or disease progression itself can significantly change dosage requirements for medications used to treat major psychiatric syndromes such as anxiety, depression, and bipolar disorder. For example, dosage requirements for lithium carbonate, commonly used to treat the manic episodes associated with bipolar disorder and the depressive episodes associated with recurrent depressive disorder, can change significantly over the course of treatment for a number of chronic diseases. Therapeutic blood levels of lithium are closely tied to sodium and water balance. Additionally, lithium has a narrow therapeutic window, and life-threatening toxicity can develop rapidly. Treatment side effects such as diarrhea, fever, vomiting, and resulting
dehydration warrant scrupulous monitoring of dosage and side effects. Careful monitoring is also indicated during pre- and postoperative periods. Another common problem among patients treated with psychotropic medication is that medications may be discontinued at specific points in the treatment process, such as the time of surgery, and not restarted. This may produce an avoidable recurrence of emotionally disabling psychiatric symptoms when the stress of a life-threatening chronic disease and its treatment is burden enough. For some patients, psychological distress does not subside with the usual supportive interventions. Unfortunately, clinically relevant and severe psychiatric syndromes are often unrecognized by nonpsychiatric care providers. Particularly, as a chronic illness progresses, anxiety and depression may occur in greater numbers of patients and with greater intensity. One of the reasons that it may be difficult to detect serious anxiety and depression in patients is that several of the diagnostic criteria used to evaluate their presence, such as lack of appetite, insomnia, decreased sexual interest, psychomotor agitation, and diminished energy, may overlap with usual disease and treatment effects.

Additionally, health care providers may confuse their own fears about chronic illness with the emotional reactions of their patients (e.g., “I too would be extremely depressed if I were in a similar situation”).

The Coexisting Nature of Psychiatric and Medical Symptoms

Depression and anxiety are appropriate to the stress of having a serious illness, and the boundary between normal and abnormal symptoms is often unclear. Even when diagnostic criteria are met for a major depressive episode or anxiety disorder, there is disagreement regarding the need for psychiatric treatment as psychiatric symptoms may improve upon initiation of medical treatment. A major source of diagnostic confusion is the overlap of somatic symptoms associated with several chronic illnesses and their treatments and those pathognomonic to depression and anxiety themselves (e.g., fatigue, loss of appetite, weakness, weight loss, restlessness, agitation). Separating out whether a symptom is due to depression, anxiety, the medical illness and its treatment, or a combination of factors is often exceedingly difficult.

Figure 19–1 diagrams the overlap between the symptoms of a chronic medical condition and/or its treatment effects and the clinical manifestations of anxiety or depression. The symptoms of anxiety or depression may be intrinsic to the medical disorder or induced by certain treatment agents. Symptoms may cease when the medical disorder is treated or the medication is discontinued or decreased. Whether the psychiatric symptoms have a primary psychiatric etiology, occur following the medical diagnosis or receive equal causal contributions from medical, and psychiatric sources, neurovegetative symptoms are not reliable assessment parameters and treatment may be delayed or never treated.

Anxiety or Depression with a Medical or Pharmacological Etiology

During progressive or active treatment phases of a chronic disease, symptoms of anxiety or depression may recur at various intervals relative to a specific causative agent, the stress associated with the illness or a combination of those as well as other factors. Diagnostic data from earlier points, both before the onset of the current illness and at various points along the illness course, are vital and should routinely be incorporated into the plan of care. As psychiatric symptoms become more prevalent within the context of the lengthening chronic illness trajectory, attention to the collection of this diagnostic information is a vital and intrinsic aspect of quality comprehensive care. History and physical, medication history, mental status, psychosocial and psychiatric histories (see Table 19–3 for screening instruments), electrocardiogram, comprehensive laboratory tests including toxicology screening, and relevant family information regarding available support systems, changes in lifestyle and functioning will promote accurate assessment and close monitoring throughout the palliative
care trajectory. This information will assist the health care team in determining the etiology of anxiety and depressive symptoms and, as such, treat and monitor them appropriately.

Some patients may have a primary psychiatric disorder that precedes the diagnosis of their chronic medical condition. This situation is increasingly encountered in primary care and chronic illness treatment settings. During the diagnostic phase, fear and anxiety are expected reactions to the diagnosis of a life-threatening or potentially life-threatening disease. Heightened apprehension coincides with the anticipated course of treatment, uncertainty, and concerns about the potential impact on lifestyle. These initial responses usually resolve in a few weeks with the support of family and friends, use of personal resources, provision of professional care, and hope.45,46 Lingering reports of feeling weak, dizzy, worried, or tense and of difficulty concentrating are often confusing to providers and may suggest an anxiety disorder. When anxiety is accurately diagnosed and treated, somatic complaints often diminish. However, if symptoms are not correctly identified and treated, clinicians must rule out a worsening medical condition, and the course of illness, treatment and suffering can become needlessly prolonged.38,39

Depression occurs frequently during the recurrence and progressive disease phase. An illness course marked with recurrences engenders anxiety and fear with each relapse, as well as feelings of desperation. Individuals experiencing depression do not always present with a dysphoric effect or report distressing feelings of hopelessness and helplessness.47 Instead, they may present with somatic complaints such as dizziness, headaches, excessive fatigue, sleep disturbances, or irritability. Accurate diagnosis and treatment, including pharmacological and psychotherapeutic management and education, can expedite somatic complaints and, importantly, the underlying depressive disorder that often causes or exaggerates them.

Disturbances in appetite, sleep, energy, and concentration are hallmark symptoms of depression. However, in the medically ill, these symptoms are frequently caused by the medical illness.48 Symptoms such as fearfulness, depressed appearance, social withdrawal, brooding, self-pity, pessimism, a sense of punishment, and mood that cannot be changed (e.g., cannot be cheered up, not smiling, does not respond to good news) are considered to be more reliable. It has been recommended that assessment of these affective symptoms provides more accurate diagnostic information for depression in medically ill patients than neurovegetative symptoms commonly used in healthy individuals.48–51

Anxiety and Depression

Anxiety or Depression Precipitated by a Medical Disorder

In many cases, an anxiety or depressive disorder occurs secondary to the diagnosis of a chronic medical condition. The stress of the medical illness itself typically induces anxiety or depression. Often these symptoms diminish when treatment is explained and initiated and hope is offered. When a patient with a chronic illness experiences increasing physical dependence on others, prolonged pain, progressive loss of function and/or immobility, anxiety and depression can become severe and prolonged. Disease progression may affect body image, self-esteem, social relationships, employment, and family roles. The extent and speed at which disabling aspects of a chronic illness occur will impact an individual's ability to react and to integrate the upsetting changes and, subsequently, to develop adjustment skills. The development of adaptive coping strategies is influenced by many factors, particularly the patient's premorbid coping strategies and the availability of outside support.

Within the context of a chronic medical condition, anxiety and depression often occur simultaneously. In general, anxiety precedes depression, and depression is more likely to persevere in individuals who also have an anxiety disorder. When anxiety and depression coexist, assessment and treatment may be more challenging, underscoring an aggressive, ongoing approach to assessment and treatment.

A common but erroneous assumption by clinicians is that the psychological distress that accompanies a medical condition, even when it is severe and unremitting, is natural and expected and, therefore, does not require or respond to treatment. This is particularly true when hope for a cure is unavailing or the prognosis is grave, leading to underrecognition and undertreatment of disabling symptoms and needlessly prompting suffering.42 Receiving a life-threatening medical diagnosis and undergoing invasive treatment are potent catalysts for an acute stress response that is not typically expected, planned for, or routinely addressed in health care settings. Providers' dominant concerns are usually centered around treatment options, the pursuit of a cure, improving prognosis, and relieving physical discomfort. Often, providers are desensitized to the intrusiveness of medical protocols and treatment environments. Most patients are not comfortable and are not encouraged to address feelings of helplessness, dependency, or fear with professional or family care providers. In fact, they often avoid such discussions to decrease burden on others, and untreated psychological symptoms may lead to a diagnosis of posttraumatic stress disorder. Posttraumatic stress disorders (PTSD), typically induced by exposure to extreme stress and/or trauma, increasingly are being linked in the literature to medical treatment situations. Providers are apt to confuse PTSD symptoms such as avoidance and withdrawal as non-pathological responses, e.g., acceptance adjustment. It is common for providers to hear “I do not remember anything about the hospitalization; it is a blur. I feel like I was in a daze... ask my wife/husband... my memory isn’t so great.”

In the treatment of PTSD, psychopharmacological agents alone are inadequate and must be accompanied by aggressive psychotherapeutic interventions, education and support. PTSD is best treated by a professional with skill treating this disorder. Routine psychiatric assessment and the availability of prompt treatment across the palliative care trajectory is critical to reduce the prevalence and morbidity of posttraumatic stress disorders that occur in response to medical diagnosis and treatment.35

Assessment and Screening Considerations

Assessment of Anxiety

The experience of anxiety is universal, especially when a person has a serious chronic illness. Anxiety is a vague, subjective feeling of apprehension, tension, insecurity, and uneasiness, usually without a known specific cause. Normally, anxiety serves as an alerting response resulting from a real or perceived threat to a person's biological, psychological, or social integrity, as well as to self-esteem, identity, or status. This alert occurs in
response to actual happenings or to thoughts about happenings, in the past, present, or future. The greater the perceived threat, the greater the anxiety response. A wide variety of signs and symptoms accompany anxiety along the continuum of mild, moderate, severe, and panic levels. Table 19–6 illustrates how anxiety affects attention, learning, and adaptation, all of which are essential to coping during the palliative care trajectory. Anxiety responses can be adaptive, and anxiety can be a powerful motivating force for productive problem-solving. Talking, crying, sleeping, exercising, deep breathing, imagery, and relaxation techniques are adaptive anxiety-relief strategies. Responses to anxiety also can be maladaptive and may indicate psychiatric disorder, but not all distressing symptoms of anxiety indicate a psychiatric disorder. Table 19–4 lists anxiety symptoms that indicate a psychiatric disorder and call for psychiatric assessment and treatment. Skill in early recognition of anxiety is crucial so that care providers can intervene immediately to alleviate symptoms, to prevent escalation and loss of control, and to enable adjustment and coping. Anxiety is interpersonally contagious. As a result, therapeutic effectiveness can be severely compromised when care providers fail to recognize and manage their own anxiety.

### Table 19–6
Symptoms of Anxiety and Effects on Attention, Learning, and Adaptation

<table>
<thead>
<tr>
<th>Level</th>
<th>Symptoms</th>
</tr>
</thead>
</table>
| **Mild** | Awareness, alert attention, skill in seeing relationships or connections available for use  
Notices more than previously, ability to observe improved  
If the person has well-developed learning and adaptive skills, will be able to use all steps in the learning process, from observing and describing to analyzing, testing, and using what is learned |
| **Moderate** | Perceptual field is narrowed, ability to observe decreased, does not notice peripheral stimuli but can notice more if directed to do so (selective inattention)  
If the person has well-developed learning and adaptive skills, will be able to use all steps in the learning process, from observing and describing to analyzing, testing, and using what is learned |
| **Severe** | Perceptual field is greatly reduced, focus on one detail or scattered details  
May be able to notice what is pointed out by another person, but as anxiety escalates will be unable to attend  
May dissociate to prevent panic (i.e., fail to notice what is happening in reference to self)  
Even with well-developed learning and adaptive skills, behavior will orient toward getting immediate relief  
Automatic (not requiring thought) behaviors used to reduce anxiety |
| **Panic** | Feelings of panic, awe, dread  
Previous foci of attention “blown up” or scattering of details increased  
Tendency to dissociate to prevent panic  
Inability to focus attention even when directed by another person  
Even with well-developed learning and adaptive skills, behavior will orient toward getting immediate relief  
Automatic (not requiring thought) behaviors used to reduce anxiety |

### Assessment of Depression

Often underrecognized and undertreated, depression has the potential to decrease immune response, decrease survival time, impair ability to adhere to treatment, and impair quality of life. The assessment of depression in any setting depends on the provider’s awareness of its potential to occur. In addition, providers must be cognizant of the risk factors associated with depression and its key signs, symptoms, and historical aspects. In addition to medical comorbidity, risk factors that favor the development of a depressive disorder include prior episodes of depression, family history of depression, prior suicide attempts, female gender, age under 40 years, postpartum period, lack of social support, stressful life events, personal history of sexual abuse, and current substance abuse. The experience of chronic and progressive disease may increase dependence, helplessness, and uncertainty and generate a negative, self-critical view. Cognitive distortions can easily develop, leading to interpretation of benign events as negative or catastrophic. Motivation to participate in care may be diminished, leading to withdrawal. Patients may see themselves as worthless and burdensome to family and friends. Family members may find themselves immobilized, impatient, or angry with the patient’s lack of communication, cooperation, or motivation.

### Cultural Considerations

Culture can be a powerful influence on the occurrence and presentation of psychiatric morbidity. In some cultures, anxiety and depression may be expressed through somatic symptoms rather than affective/behavioral symptoms such as guilt or sadness. Complaints of “nerves” and headaches (in Latino and Mediterranean cultures); of weakness, tiredness, or “imbalance” (in Chinese or Asian cultures); of problems of the “heart” (in Middle Eastern cultures); or of being “heartbroken” (among the Hopi) may be depressive equivalents. Cultures may differ in judgments about the seriousness of dysphoria; for example, irritability may be a greater concern than sadness or withdrawal. Experiences distinctive to certain cultures, such as fear of being hexed or vivid feelings of being visited by those who
Conceptual and Diagnostic Considerations

The conceptualization of psychological distress is varied. Depression in particular, has a variety of meanings and has been used to describe a broad spectrum of human emotions and behaviors, ranging from expected, transient, and nonclinical sadness following upsetting life events to the clinically relevant extremes of suicidality and major depressive disorder. Depression is common among people with chronic illness. The term “depressive syndromes” refers to a specific constellation of symptoms that comprise a discrete psychiatric disorder, such as major depression, dysthymia, organic affective disorder, and adjustment disorder with depressed features. Depressive symptoms describe varying degrees of depressed feelings not necessarily associated with psychiatric illness. Five major theoretical viewpoints have been used to understand and treat depression. In the psychoanalytic view, depression represents the introjection of hostility subsequent to the loss of an ambivalently loved object.46 Cognitive views emphasize the mediating role that distorted and negative thinking plays in determining mood and behavior.47 In the sociological view, depression is a social phenomenon in which a breakdown of self-esteem involves the loss of possessions such as status, roles and relationships, and life meaning.48 Cultural and societal factors, including illness, increase vulnerability to depression. The biological view of depression emphasizes genetic vulnerability and biochemical alterations in neurotransmitters.49 In studies of medically ill patients, depression is often equated with a crisis response, in which demands on the individual exceed the ability to respond.50

Conceptual viewpoints are important to the extent that they influence the understanding and subsequent treatment of the psychiatric symptoms experienced by patients with chronic physical illness. Diverse conceptualizations do not diminish the ability to plan and deliver effective care and most often simply offer complementary ideas concerning the etiological significance of symptoms. In many health care settings, nurses have the most patient contact and are likely to talk with individuals about their physical and emotional problems and thus to detect psychiatric symptoms and syndromes. Specific screening instruments, such as those listed in Table 19–5, may be used for assessment. In addition, direct questioning and clinical observation of mood, behavior, and thinking can be carried out concomitant with physical care. Questions related to mood may include the following: How have your spirits been lately? How would you describe your mood now? Have you felt sad or blue? Questions about behavior relate to sleeping patterns, appetite, activity level, and changes in energy: How are you sleeping lately? How much energy do you have now compared with 1 month or 6 months ago? Have you experienced recent changes in your appetite? Have you lost or gained weight? What do you usually do to cope with stress (talk to someone? go to a movie? work? exercise? drugs? alcohol?)? Questions related to cognition are as follows: What do you see in your future? What are the biggest problems facing you now? Are you as interested as usual in your family and friends, work, hobbies, etc.? Have you felt satisfied with yourself and with your life? Can you concentrate as well as you usually can? Do you have family or close friends readily available to help you? Do you feel able to call on them? As noted previously, disturbances in appetite, sleep, energy, and concentration may be caused by the illness and not necessarily indicative of depression.

Screening for Anxiety and Depression

In chronic illness settings, the need for routine psychiatric screening has been well documented for identifying patients at high risk for psychiatric morbidity, as well as to identify those who can benefit from early-intervention programs. Patients may require different interventions based on their placement on the distress continuum. Researchers51 concluded that newly diagnosed patients who are highly distressed can benefit from evaluation and treatment for psychiatric consequences of illness and that adaptation to the disease can be improved through the use of psychosocial interventions and close monitoring. A number of tools have been developed to screen for psychological distress but have not been consistently incorporated into clinical care.52–53 One tool that is easy to administer, reliable, and palatable to patients is the Distress Thermometer. This tool, developed by a team led by Dr. Jimmie Holland at Memorial Sloan Kettering Cancer Center, is similar to pain measurement scales that ask patients to rate their pain on a scale from 0 to 10, and consists of two cards. The first card is a picture of a thermometer, and the patient is asked to mark his or her level of distress. A rating of 5 or above indicates that a patient has symptoms indicating a need to be evaluated by a mental health professional and potential referral for services. The patient is then handed a second card and asked to identify which items from a six-item problem list relate to the patient’s distress, that is, illness-related, family, emotional, practical, financial, or spiritual. This tool is part of the National Comprehensive Cancer Network (NCCN) distress-management practice guidelines in oncology. This interdisciplinary workgroup chose the term “distress management” because it was “more acceptable and less stigmatizing than psychiatric, psychosocial or emotional,” and could be defined and measured by self-report.54

Again, striving for simplicity and clinical utility, Harvey Chochinov and colleagues compared the performance of four brief screening measures for depression in the terminally ill.55 They found that asking the question “Are you depressed?” was reliable and valid for diagnosing depression and was extraordinarily useful in care of the terminally ill. Both the NCCN Practice Guidelines for distress management and the simple three-word screening sentence for depression can easily be incorporated into daily clinical practice.
Addressing Deficits in Case-finding Strategies

Individuals are living longer with chronic illnesses within the context of aggressive physically and psychologically debilitating treatments. These trends promise to continue, and further study is needed to identify effective approaches to treatment. Available data clearly support a policy of routine psychological assessment in chronic-illness settings. Additional studies are needed to support intervention development that, at a minimum, will likely lead to improved quality of life for patients and cost savings at the systems level. In clinical settings, detection and case identification are particularly difficult. As mentioned, this is due to several factors including: the high prevalence of clinically significant “subsyndromal” psychiatric symptoms in medically ill samples (symptoms not severe enough or of sufficient duration to be classified as a psychiatric disorder), and the overlapping nature of physical and neurovegetative symptoms, such as fatigue, changes in appetite, sleep, and sex drive. Different clinical sites have their own unique limitations, including lack of knowledge, comfort, or time by health professionals to assess patients for these symptoms. Consequently, recognition of significant psychological distress (psychiatric morbidity) is seriously impeded in clinical settings. Clinicians need to be trained to recognize the prognostic importance of comorbid medical illness and psychiatric symptoms and to understand how the subtleties of case identification can affect treatment planning. The range in severity of psychiatric symptoms and the often rapid change in both psychiatric and physical symptoms across the treatment trajectory create both a great variance and the need to observe and record the dynamic interchange between physical and psychological phenomena over a small time span. The difficulties in case identification discussed may be highlighted by the severity of physical symptoms and the low prevalence of prior mood disorder. The presence of acute physical illnesses places the individuals under severe physiological as well as psychological and psychosocial stress. In addition, patients are often removed from their usual social support systems to receive treatment and are exposed to psychosocial stressors unique to the treatment setting (e.g., dependency on hospital staff, unfamiliar and sometimes painful diagnostic and therapeutic procedures, altered eating, bathing, and sleep routines, and uncertain prognosis). Symptom assessments must strike a balance between overly inclusive (e.g., mistakenly treating the fatigue of cancer treatment as depression) and overly exclusive (e.g., erroneously dismissing the patient’s mood symptoms as “understandable”). Case identification is a crucial first step. The approach to identifying psychiatric symptoms potentially confounded by medical illnesses must be defined explicitly. Choice of an inclusive approach avoids premature exclusion of relevant phenomena. The use of similar screening instruments across clinical sites would greatly facilitate comparisons of information and standardization of assessment and case-finding guidelines.

Suicide

Suicide is the ninth leading cause of death in the United States. Five percent of suicides occur in patients with chronic medical illnesses, with spinal cord injuries, multiple sclerosis, cancer, and human immunodeficiency virus disease. Because of underreporting, statistics underestimate the magnitude of suicide; intentional overdoses by the terminally ill and intentional car accidents are rarely labeled as suicides. The strongest suicide predictor is the presence of a psychiatric illness, especially depression and alcohol abuse, although a chronic deteriorating medical illness with perceived poor health, recent diagnosis of a life-threatening illness, and recent conflict or loss of a significant relationship also are considered to be predictive. Males, over age 45 years, and living alone and lacking a social support system are risk factors. In one study, hopelessness was found to be more important than depression as a clinical marker of suicidal ideation in the terminally ill. Individuals with progressive chronic illness, particularly during the terminal stages, are at increased risk for suicide. Other cancer-related risk factors include oral, pharyngeal, or lung cancer; poor prognosis; confusion and delirium; inadequately controlled pain; and the presence of deficits, such as loss of mobility, loss of bowel or bladder control, amputation, sensory loss, inability to eat or swallow, and exhaustion. The highest-risk patients are those with severe and rapidly progressive disease producing rapid functional decline, intractable pain, and/or history of depression, suicide attempts, or substance abuse.

Physician-Assisted Suicide

Whereas suicide is the intentional ending of one’s own life, physician-assisted suicide (PAS) refers to a physician acting to aid a person in the ending of his or her life. Public demand for PAS has been fueled by burdensome, exhausting, and expensive dying in acute care settings. It is highly controversial; the American Medical Association, the American Nurses Association, and the National Hospice and Palliative Care Organization have taken strong positions against it. Implications for health care providers include the following: to be knowledgeable about the legal and moral/ethical aspects of PAS; to do a personal evaluation and prepare responses for situations with patients where the topic may arise; to improve education about pain management, symptom control, and related issues in the care of dying and seriously ill patients; to conduct rigorous research on the attitudes and practices of health care professionals with respect to assisted suicide; and to develop effective mechanisms to address conflicts. There is an ongoing debate about the legalization of PAS. Only in Oregon have the voters approved legalization of PAS. The controversy potentially affects pain management in palliative care. Current efforts to create a federal ban on PAS may have a “chilling” effect on the widely supported approach to pain management.
in terminal care of high doses of opiates, regardless of secondary effects on respiration and length of life. Some fear that providing adequate pain relief might be seen as assisting the patient to die.76 Although the Oregon law remains in dispute, the public dialogue in that state led to palliative care reform that significantly improved end-of-life care in Oregon.75 Events in Oregon highlight care as a priority and increase the understanding about the distinction between assisting suicide and honoring patient preferences for limiting life-sustaining treatment.75 Patient concerns most often related to desire to suicide are unrelieved pain, poorly managed symptoms, depression, worries about loss of control, being a burden, being dependent on others for personal care, and loss of dignity.76 Valente and Trainor46 identified poor quality of life, failed requests for treatment withdrawal, and distressing treatments as typical reasons for suicide in the critically ill. Further, patient requests for PAS are not rare, and physicians do provide such services, even though they are not legal.77 Requests to physicians may also be indirect, as in the reported case of a patient asking for pain relief with the unspoken intent to cause death.78 To further complicate the issue for health care providers, requests for suicide may be rational and not simply a symptom of depression.76 Rationality has been defined as the capacity to deliberate, to communicate in relationships, and to reflect on and to examine one’s own values and purposes.76 The accepted criteria for rational suicide among adults with terminal illness include the following: rational considerations, understandable motives, careful planning, review of alternatives, absence of coercion, and recognition of consequences.76 The patient’s decisional capacity may be impaired by agitation, disorientation, major depression, poor reality orientation, grief and loss, medications, effects of illness, and ambivalence. Particularly in these circumstances, a formal psychiatric evaluation is warranted. See Chapter 59, Palliative Care and Requests for Assistance in Dying, for a more in-depth review.

Assessment of Suicide Risk

Assessment and treatment of depression, often overlooked in chronic-illness treatment settings, is a key suicide-prevention strategy. In addition, managing symptoms, communicating, and helping patients to maintain a sense of control are vitally important prevention strategies. An assessment of depression should always include direct questions about suicidal thinking, plans or attempts, despair or hopelessness, distress from poorly managed symptoms, and personal or family history of suicidal ideation, plans, or attempts.76 When any indicator of suicide risk is recognized, risk factors, clues, suicidal ideation, level of depression, hopelessness and despair, and symptom distress should be thoroughly evaluated to estimate individual lethality. The rationality of the suicidal request or intent must also be evaluated. The nurse should interview the patient and family members to find out why the patient is thinking about suicide now.76 Find out what method the patient is considering and whether the means are available. Ask the patient what has prevented suicide before and if he or she wants help or hopes someone else will decide.76 Most people are relieved to be asked about suicidal thoughts because it opens communication. Initial and periodic evaluation of suicidal potential is necessary for patients with a history, thoughts, or risk factors of suicide.

Recognition of Clues

Suicidal persons usually give verbal and/or behavioral clues, such as isolated or withdrawn behavior or death wishes or death themes in art, writing, play, or conversation. Clues may be subtle or obvious, for example, joking about suicide, asking questions concerning death (e.g., “How many of these pills would it take to kill someone?”), comments with a theme of giving up, or statements that indicate hopelessness or helplessness. Resistance or refusal of treatments, food, or fluids may indicate suicidal ideation or intent and require further assessment.74,76 Keys to determining lethality are suicide plan, method, intended outcome (e.g., death or rescue), and availability of resources and ability to communicate.74,76 Lethal means include guns, knives, jumping from heights, drowning, or carbon monoxide poisoning. Other potentially lethal means include hanging or strangulation (using strong pieces of twine, rope, electric cords, sheets), taking high doses of aspirin or Tylenol, being in a car crash, or undergoing exposure to extreme cold. Low to moderately lethal methods are wrist cutting and mild aspirin overdose.

Suicide Interventions

Severely depressed and/or potentially suicidal patients must be identified as soon as possible to ensure a safe environment and appropriate treatment. Prompt action should be taken including provision of safety, supervision, and initiation of psychiatric evaluation. A patient with an immediate, lethal, and precise suicide plan needs strict safety precautions such as hospitalization and continuous or close supervision. The low-risk patient should not be underestimated. If circumstances change, risk could change. In all cases, notify the primary provider, and document the patient’s behavior and verbatim statements, suicide assessment, and rationale for decisions, as well as the time and date the provider was notified.76 If the provider is not responsive to the report of the patient’s suicidal ideation, it is important to maintain observation and to pursue psychiatric consultation. The motivation for suicide can be reduced through palliative care interventions such as improved pain and symptom management; referral and treatment for depression or other psychiatric disorders; discussion of alternative interventions to improve quality of life; referral to spiritual, social, and psychiatric resources; and education and accurate facts about options for terminal care or end-of-life decision-making. Openness to talking about suffering, distress, death preferences, and decision-making in a sensitive and understanding manner and advocacy to aid communication with others is helpful for patients and their families.76,77
Management of Anxiety and Depression

Psychosocial interventions can exert an important effect on the overall adjustment of patients and their families to chronic illness and treatment. Several studies document the beneficial effect of counseling on anxiety, feelings of personal control, depression, and generalized psychological distress. Increased length of survival from time of diagnosis has highlighted the need for psychopharmacological, psychotherapeutic, and behaviorally oriented interventions to reduce anxiety and depression and to improve quality of life for patients diagnosed with a chronic illness.

Pharmacological Interventions

Pharmacotherapy, as an adjunct to one or more of the psychotherapies, can be an important aid in bringing psychological symptoms under control.

Pharmacological Management of Anxiety. The prevalence of anxiety in medical illness is relatively high. As described in Figure 19–1, a variety of disorders have anxiety as a prominent symptom of the clinical presentation (see Tables 19–1 and 19–2), and many commonly used medications are associated with anxiety as a side effect. Studies have shown a high prevalence in cardiovascular, pulmonary, cerebrovascular, and gastrointestinal diseases, as well as cancer and diabetes. In addition, patients with a history of anxiety disorders have increased rates of diabetes, heart disease, arthritis, and physical handicaps compared to the general population. Pain, metabolic abnormalities, hypoxia, and drug withdrawal states can present as anxiety. Before instituting pharmacological treatment, any patient with acute or chronic symptoms of anxiety should be thoroughly evaluated, including a review of medications to assess the contribution of medical condition and/or medication-related etiologies for their complaints.

The following brief review of pharmacological treatment must be supplemented with other references concerning assessment, intervention, evaluation, and patient education (Table 19–7). Benzodiazepines are the most frequently used medications for anxiety in both medical and psychiatric settings. When longer-acting benzodiazepines, such as diazepam, are used in the elderly or in the presence of liver disease, dosages should be decreased and dosing intervals increased. They may suppress respiratory drive. Consultation-liaison services often use lorazepam in medically ill patients because its elimination half-life is relatively unaffected by liver disease, age, or concurrent use of selective serotonin reuptake inhibitors (SSRIs) or nefazodone. Drawbacks include amnestic episodes and interdose anxiety caused by its short half-life. The latter can be remedied by more frequent dosing. If medically ill patients need a longer-acting benzodiazepine for panic disorder or generalized anxiety disorder, clonazepam is often used because it is not affected by concurrent use of SSRIs. Clonazepam may accumulate and result in oversedation and ataxia.

in the elderly; therefore, low doses are used. Temazepam is useful as a sedative-hypnotic. Buspirone, used primarily for generalized anxiety disorder, is preferable for anxiety in the medically ill because of its lack of sedation, lack of negative effects on cognition, insignificant effect of age on elimination half-life, and limited effect of liver disease on half-life. Buspirone has almost no clinically significant interactions with drugs commonly used in general medicine. It may stimulate the respiratory drive, which makes it useful in patients with pulmonary disease or sleep apnea. Cyclic antidepressants are well established as anxiolytic agents, which are particularly effective in the treatment of panic disorder and in generalized anxiety disorder. If these drugs are used for anxiety in depressed medically ill patients or used because of their sedating properties in patients with major depression or panic disorder, the side effects must be carefully considered. Potentially deleterious side effects in the medically ill are sedative, anticholinergic, orthostatic hypotensive, and quinidine-like. Liver disease and renal disease may affect metabolism and excretion of the drug and, therefore, require careful dosage titration. Other drugs that may be used for anxiety include the β-adrenergic blocking agents, antihistamines, monoamine oxidase inhibitors, and neuroleptics. Beta-adrenergic blocking agents may be used for milder forms of generalized anxiety, but there are cautions and contraindications in the presence of pulmonary disease, diabetes, and congestive heart failure. Antihistamines are sometimes used, although the effects are largely nonspecific and sedative. Side effects, such as sedation and dizziness, can be significant for medically ill patients. Monoamine oxidase inhibitors are rarely used in the medically ill because of the precautions that must be taken to prevent drug interactions. Neuroleptics, such as haloperidol in low doses, are used for anxiety associated with severe behavioral agitation or psychotic symptoms. When anxiety develops in the context of the terminal stages of cancer, it is often secondary to hypoxia and/or an untreated pain syndrome. Intravenous opiates and oxygen if hypoxia is present are usually an effective palliative treatment. Anxiety and depression are often quite effective but underutilized in medical settings. Medical illnesses and the medications required to treat or manage symptoms may impose significantly modified prescribing regimens on the use of antidepressants. Therefore, it is necessary to evaluate the possible role of existing medical conditions and medications that could cause the depressive symptoms. Other general guidelines include: (1) use the medication with the least potential for drug–drug interactions and for adverse effects based on the patient’s drug regimen and physiological vulnerabilities, and the greatest potential for improving the primary symptoms of the depression; (2) begin with low dosage, increase slowly, and establish the lowest effective dosage; and (3) reassess dosage requirements regularly.

In the past, antidepressant drug selection was limited by the nearly sole availability of tricyclic antidepressants, but new drugs, such as the SSRIs, bupropion, and venlafaxine, have vastly simplified pharmacological treatment of depression in the medically ill. No one medication is clearly more effective than another. The SSRIs have fewer long-term side effects than the tricyclic antidepressants and, in general, are the first line of pharmacological antidepressant treatment unless specific side effect profiles associated with other classes of drugs are desired.

Psychostimulants such as dextroamphetamine and methylphenidate have been useful in the treatment of depression in medically ill patients. Advantages include rapid onset of action and rapid clearance if side effects occur. They can also counteract opioid-induced sedation and improve pain control through a positive action on mood. Common side effects of psychostimulants include insomnia, anorexia, tachycardia, and hypertension, although incremental dosage increases allow adequate monitoring of therapeutic versus side effects. In patients with cardiac conduction problems, stimulants may be the treatment of choice. In medically ill patients, a 1- to 2-month trial can provide remission from depression even after discontinuation of the drug. Different studies have shown a 48% to 80% improvement in depressive symptoms, and this class of medication is often quite effective but underutilized in medical settings (Table 19–8).

Certain medications and treatment agents can produce severe depressive states. As reiterated throughout this chapter, a diagnosis of major depression in medically ill patients relies heavily on the presence of affective symptoms such as hopelessness, crying spells, guilt, preoccupation with death and/or suicide, diminished self-worth, and loss of pleasure in most activities, for example, being with friends and loved ones. The

Pharmacological Management of Depression. Patients with chronic illness commonly exhibit transient depressive symptoms at various points in the disease trajectory, particularly during the palliative care period when a hope for cure is no longer possible. As explained previously, depressive symptoms can be caused by the medical disorder itself, associated with medications used for treatment or symptom management, or caused or worsened by the stress related to coping with illness. Depression can also predate and recur with the medical illness. To further complicate matters, individuals with medical illness are often older, with potentially greater risk of adverse effects from both psychotropic and nonpsychotropic medications. Medical illnesses and the medications required to treat or manage symptoms may impose significantly modified prescribing regimens on the use of antidepressants. Therefore, it is necessary to evaluate the possible role of existing medical conditions and medications that could cause the depressive symptoms. Other general guidelines include: (1) use the medication with the least potential for drug–drug interactions and for adverse effects based on the patient’s drug regimen and physiological vulnerabilities, and the greatest potential for improving the primary symptoms of the depression; (2) begin with low dosage, increase slowly, and establish the lowest effective dosage; and (3) reassess dosage requirements regularly.

(continued)
neurovegetative symptoms that usually characterize depression in physically healthy individuals are not good predictors of depression in the medically ill because disease and treatment can also produce these symptoms. A combination of psychotherapy and antidepressant medication will often prove useful in treating major depression in medically ill patients.\textsuperscript{88} Peak dosages of antidepressants, regardless of drug class, are usually substantially lower than those tolerated by physically healthy individuals. Antidepressant medications may take $2$ to $6$ weeks to produce their desired effects. Patients may need ongoing support, reassurance, and monitoring before experiencing the antidepressant effects of medication. It is essential that patients are monitored closely by a consistent provider during the initiation and modification of psychopharmacological regimens. Patient education is essential in this area to decrease the possibility of nonadherence to the medication regimen.

### Psychotherapeutic Modalities

Psychosocial interventions are defined as systematic efforts applied to influence coping behavior through educational or psychotherapeutic means.\textsuperscript{18} The goals of such interventions are to improve morale, self-esteem, coping ability, sense of control, and problem-solving abilities, and to decrease emotional distress. The educational approach is directive, using problem-solving and cognitive methods. It is important that the educational approach both clarify medical information that may be missed due to fear and anxiety or misconceptions and/or misinformation regarding illness and treatment, and normalize emotional reactions throughout the illness trajectory. The psychotherapeutic approach uses psychodynamic and exploratory methods to help the individual understand aspects of the medical condition such as emotional responses and personal meaning of the disease. Psychotherapeutic interventions, as opposed to educational interventions, should be delivered by professionals with special training in both mental health and specific interventional modalities as applied to patients with chronic medical illnesses and palliative care needs. Psychotherapy with a patient who has cancer should maintain a primary focus on the illness and its implications, using a brief therapy and crisis-intervention model.\textsuperscript{78} Expression of fears and concerns that may be too painful to reveal to family and friends is encouraged. Normalizing emotional distress, providing realistic reassurance and support, and bolstering existing strengths and coping skills are essential components of the therapeutic process. Gathering information about previous associations with the medical condition experienced through close relationships can also be instrumental in clarifying patients’ fears and concerns and establishing boundaries for and differences from the current situation.

Depending on the nature of the problem, the treatment modality may take the form of individual psychotherapy, support groups, family and marital therapy, or behaviorally oriented therapy such as progressive muscle relaxation and guided imagery. A primary role for clinicians is to facilitate a positive adjustment in patients under their care. Periodic emotional distress and coping problems can be expected during the palliative-care trajectory and monitored routinely. Emotional display is not the same as maladaptive coping. Understanding an individual’s unique circumstances can assist nurses in supporting the constructive coping abilities that seem to work best for a particular patient.\textsuperscript{78}

Psychotherapeutic Interventions Targeted to Symptoms of Anxiety

Anxiety responses can be thought of as occurring along a continuum, from mild to moderate to severe to panic. Lazarus and Folkman’s \(^\text{92}\) differentiation of problem-focused coping and emotion-focused coping provides a framework for intervention strategies matched to the continuum of responses (Table 19–9).

patient was taking medications for “nerves,” depression, or insomnia will help to determine whether drugs were inappropriately discontinued or whether anxiety symptoms predated the current illness. In addition, ask about over-the-counter medications, illegal drugs, alcohol intake, and smoking history. Documentation and communication of findings are essential to enhance teamwork among providers.

Frequently, patients can identify the factors causing their anxiety, as well as coping skills effective in the past, and when they do, their discomfort decreases. Anxiety may be greatly reduced by initiating a discussion of concerns that are painful, frightening, or shameful, such as being dependent or accepting help. Use open-ended questions, reflection, clarification, and/or empathic remarks, such as “You’re afraid of being a burden?” to help the patient to identify previously effective coping strategies and to integrate them with new ones. Use statements such as “What has helped you get through difficult times like this before?” “How can we help you use those strategies now?” or “How about talking about some new strategies that may work now?” Encourage the patient to identify supportive individuals who can either help emotionally or with tasks.

**Preventive Strategies.** Preventive strategies can help to maintain a useful level of anxiety, one that enhances rather than interferes with problem-solving (see Table 19–9). Effective preventive strategies that can be used by all providers involved with the patient follow26,90:

1. Provide concrete objective information. Fear of the unknown, lack of recent prior experience, or misinterpretations about an illness, procedure, test, or medication, especially when coupled with a tendency to focus on emotional aspects of experiences, may be a source of anxiety. Help patients and families know what to expect, and focus attention by realistically describing the potentially threatening experience with concrete objective information.90 Describe both the typical subjective (e.g., sensations and temporal features) and objective (e.g., timing, nature of environment) features of stressful health care events using concrete terminology. Avoid qualitative adjectives, such as “terrible.” Also known as mental rehearsal and stress inoculation, concrete information increases the patient’s understanding of the situation, allows for preparation under less emergent and more supportive conditions, and facilitates coping. Encourage the patient to ask questions, and then match the detail of the preparatory information to the request. Since anxiety hinders retention, use of understandable terms and repetition is helpful. Too much information at once may increase anxiety.

2. Ensure stressful event warning before the event. For example, a person may experience magnetic resonance imaging as entrapping or traumatic or the placement of a central line as painful and threatening. Giving time to anticipate and mentally rehearse coping with the experience helps the person to maintain a sense of control and endure the procedure.

3. Increase opportunities for control. Illness can seriously disrupt a person’s sense of control and increase anxiety. Help the patient to make distinctions between what is controllable, partially controllable, or not controllable. Focus on what is controllable or partially controllable and create decision-making and choice opportunities that fit the patient’s knowledge. Ask patients to make choices about scheduling the day of the visit and the readiness for and timing of procedures and interventions.

4. Increase patient and family participation in care. Participation in care helps directly in coping and can be taught to both the patient and family members. Participation may reduce helplessness and increase a sense of control. Patients and family members may vary in their interest in participating and in their ability to do so. Often, female family members are more likely to be caregivers. Other factors influencing the ability to participate include family roles such as spouse, parent, and sibling; quality of relationships; presence or absence of conflicts; and other commitments, such as work or other family roles. Cultures also vary in expectations and the duty or obligation about caregiving based on gender or family position. Participation may also help with the resolution of ineffective denial when a person’s condition is deteriorating. Family members who are caring for a person may recognize and adjust to the deterioration.

5. Encourage self-monitoring and the use of a stress diary. Self-monitoring of stress is a cognitive-behavioral intervention. Ask the patient to record the situations, thoughts, and feelings that elicit stress and anxiety. The patient may record incidences of treatment-related stress, illness-related stress, or other unrelated anxiety-provoking situations. Not only does this intervention provide assessment information, it also enhances collaboration with the patient and helps the patient understand the relationship between situations, thoughts, and feelings.

6. Acknowledge fears. Encourage and listen to the expression of feelings. Avoid denying the existence of problems or reassuring anxious people that “everything will be fine.” Structure your availability. Refrain from avoiding anxious persons or their fears. Avoidance is likely to increase vulnerability, isolation, helplessness, and anxiety. Early structured intervention is more economical of time and more effective.

7. Explore near-miss events. Past or current exposure to a near-miss event is a potent generator of extreme stress and anxiety, with heightened vigilance. A near-miss is a harrowing experience that overwhelms the ability to cope. It may be a one-time experience, such as a person’s own near-death experience, the cardiac arrest of another person in similar circumstances, or
something faced repeatedly, such as daily painful skin and wound care. Near-misses should be explored, fears acknowledged and realistically evaluated in view of the person’s situation, and help given in developing coping strategies.

8. Manage symptoms. Managing symptoms such as pain, dyspnea, and fatigue is an essential part of promoting self-control. Symptoms such as pain signal threat and may lead to worries about the meaning of the symptom and whether necessary treatments will be worse or more frightening. Ensure pain control, especially before painful or frightening procedures. Severe anxiety may increase the perception of pain and increase the requirement for analgesia. Symptom management reduces distress and allows for rest.

9. Structure uncertainty. Even when there are many unknowns, the period of uncertainty can be framed with expected events, procedures, updates, and meetings with providers.

10. Reduce sensory deprivation. Sensory deprivation and isolation can heighten attention to various signals in the environment. Without the means for the patient to accurately interpret the signals, to be reassured, and to feel in control, the signals take on frightening meanings, such as abandonment and helplessness. Feeling isolated and helpless increases the sense of vulnerability and danger.

11. Build hope. Provide information about possible satisfactory outcomes and means to achieve them. Hope also may be built around coping ability, sustaining relationships, revising goals such as pain-free or peaceful death, and determination to endure. Many additional suggestions are provided in this text.

Treatment Strategies. When it is evident that the person’s anxiety level has escalated to the point of interfering with problem solving or comfort, the following strategies may be helpful.

1. Presence of supportive persons. Familiar and supportive people, a family member, friend, or staff member can act as an “emotional anchor.” Family and friends may need coaching to enable them to help in the situation without their own anxiety increasing.

2. Expression of feelings, doubts, and fears. Verbalizing feelings provides the opportunity to correct or restructure unrealistic misconceptions and automatic anxiety-provoking thoughts. Accurate information allows restructuring of perceptions and lends predictability to the situation. Aggressive confrontation of unrealistic perceptions may reinforce them and is to be avoided.

3. Use of antianxiety medications. If medications are used, they should be given concurrently with other interventions and monitored. Use caution to avoid delirium from toxicity, especially in the aged person.

4. Promoting patient control and readiness. If a patient is very frightened of a particular procedure, allow time for the patient to regain enough compos- sure to make the decision to proceed. Forging ahead when a patient is panicked may appear to save time in the immediate situation, but it will increase the patient’s sense of vulnerability and helplessness, possibly adding time over the long term.

5. Management of panic. When anxiety reaches panic, use presence and acknowledgment: “I know you are frightened. I’ll stay with you.” Communicate with repetition and simplicity. Guide the person to a smaller, quieter area away from other people and use quiet reassurance. Maintain a calm manner and reduce all environmental stimulation. Help the patient to focus on a single object (see below), and guide the patient in recognizing the physical features of the object while breathing rhythmically. Consider using prescribed anxiolytic medication.

6. Massage, touch, and physical exercise. For those who respond well to touch, massage releases muscle tension and may elicit emotional release. Physical exercise is a constructive way of releasing energy when direct problem-solving is impossible or ineffective because it reduces muscle tension and other physiological effects of anxiety.

7. Relaxation techniques. Relaxation techniques are likely to be effective for patients with mild to moderate anxiety who are able to concentrate and who desire to use them. Some techniques require learning and/or regular practice for effectiveness. Environmental awareness is reduced by focusing inward, with deliberate concentration on breathing, a sound, or an image, and suggestions of muscle relaxation. Progressive relaxation and autogenic relaxation are commonly used techniques, which require approximately 15 minutes. Relaxation and guided imagery scripts are readily available for use by clinicians.

8. Breathing techniques. Simple and easy to learn, breathing exercises emphasize slow, rhythmic, controlled breathing patterns that relax and distract the patient while slowing the heart rate, thus decreasing anxiety. Ask the patient to notice his or her normal breathing. Then ask the patient to take a few slow, deep abdominal breaths and to think “relax” or “I am calm” with each exhalation. Encourage practice during the day. Some patients are helped by seeing photographs and drawings of lungs and breathing to visualize their actions.

9. Focusing techniques. Useful for patients with episodes of severe-to-panic levels of anxiety, focusing repeatedly on one person or object in the room helps the patient to disengage from all other stimuli and promotes control. A combination of focusing with demonstration and coaching of slow, rhythmic breathing with a calm, low-pitched voice is helpful.
These techniques enhance the patient’s self-control, which is desirable when the stress reaction is excessive and the stressful event cannot be changed or avoided. Both focusing and deep-breathing techniques can be used without prior practice and during extreme stress.

10. Music therapy. Soothing music or environmental sounds reduce anxiety by providing a tranquil environment and prompting recall of pleasant memories, which interrupt the stress response through distraction or direct sympathetic nervous system action. Music most helpful for relaxation is primarily of string composition, low-pitched, with a simple and direct musical rhythm and a tempo of approximately 60 beats per minute, although music with flute, a cappella voice, and synthesizer is also effective.

11. Imagery and visualization techniques. Imagery inhibits anxiety by invoking a calm, peaceful mental image, including memories, dreams, fantasies, and visions. Guided imagery is the deliberate, goal-directed use of the natural capacities of the imagination. Using all the senses, imagery serves as a bridge for connecting body, mind, and spirit. Imagery, especially when combined with relaxation, promotes coping with illness by anxiety reduction, enhanced self-control, feeling expression, symptom relief, healing promotion, and dealing with role changes. Regular practice of imagery enhances success. Guided imagery for pain or anxiety reduction should not be attempted the first time in periods of extreme stress. Imagery in conversation is subtle and spontaneous. Often without awareness, health care providers’ questions and statements to patients include imagery. Easily combined with routine activities, the deliberate use of conversational imagery involves listening to and positive use of the language, beliefs, and metaphors of the patient. Be aware of descriptors used for the effects of medications or treatments because they affect the patient’s attitude and response. Health care providers can enhance hope and self-control if they give empowering, healing messages that emphasize how the treatment will help.

Psychotherapeutic Interventions Targeted to Symptoms of Depression

Depression is inadequately treated in palliative care, although many patients experience depressive symptoms. Goals for the depressed patient are (1) to ensure a safe environment, (2) to assist the patient in reducing depressive symptoms and maladaptive coping responses, (3) to restore or increase the patient’s functional level, (4) to improve quality of life if possible, and (5) to prevent future relapse and recurrence of depression.

Crisis Intervention. Crisis intervention is appropriate treatment for a grief-and-loss reaction and when a patient feels overwhelmed. Effective strategies also include providing guidance on current problems, reinforcing coping resources and strengths, and enhancing social supports.

Cognitive Interventions. Cognitive interventions (Table 19–10) are based on a view of depression as the result of faulty thinking. A person’s reaction depends on how that person perceives and interprets the situation of chronic illness. Patterns of thinking associated with depression include self-condemnation, leading to feelings of inadequacy and guilt; hopelessness, which is often combined with helplessness; and self-pity, which comes from magnification or catastrophizing about one’s problems. Cognitive approaches involve clarification of misconceptions and modification of faulty assumptions by identifying and correcting distorted, negative, and catastrophic thinking. Cognitive approaches are effective in treating forms of depression. Therapy is usually brief, with the primary goal of reversing and decreasing the likelihood of recurrence of the symptoms of depression by modifying cognitions. It requires effort on the part of the patient. The effect is more powerful if homework and practice are included. Cognitive restructuring is one of the strategies used in cognitive therapy. In this strategy, patients are aided in identifying and evaluating maladaptive attitudes, thoughts, and beliefs by self-monitoring and recording their automatic thoughts when they feel depressed. The patient is then helped to replace self-defeating patterns of thinking with more constructive patterns. For example, “The treatment is not working. I can’t cope; nothing works for me,” could be replaced with a rational response such as “I can cope. I have learned how to help myself and I can do it.” New self-statements and their associated feeling responses can also be written on the self-monitoring form. Over time, the patient learns to modify thinking and learns a method for combating other automatic thoughts.

Imagery rehearsal is a useful strategy for helping patients cope with situations in which they usually become depressed. The first step is to anticipate events that could be problematic, such as a magnetic resonance procedure. The patient is helped to develop constructive self-statements; then, imagery is used to provide an opportunity for the patient to mentally rehearse how to think, act, and feel in the situation. The combination of imagery with cognitive restructuring increases the effectiveness.

Interpersonal Interventions. Interpersonal interventions (see Table 19–10) focus on improved self-esteem, the development of effective social skills, and dealing with interpersonal and relationship difficulties. Interpersonal difficulties that could be a focus include role disruptions or transitions, social isolation, delayed grief reaction, family conflict, or role enactment. Psychotherapies include individual, group, and support groups led by a trained professional. Patient-led support groups or self-help groups are effective for the general chronic illness population but less able to address the needs of depressed persons.

### Complementary Therapies
- Guided imagery and visualization
- Art and music therapies
- Humor
- Aerobic exercise
- Phototherapy
- Aromatherapy and massage

Behavioral Interventions. Behavioral interventions (see Table 19–10) are based on a functional analysis of behavior and on social learning theory. These interventions are often used in combination with cognitive interventions, such as self-monitoring and imagery rehearsal. The key to the behavioral approach is to avoid reinforcement of dependent or negative behaviors. Instead, provide a contingency relationship between positive reinforcement and independent behavior and positive interactions with the environment. This approach suggests that, by altering behavior, subsequent thoughts and feelings are positively influenced. It is helpful to structure this approach using the following self-care functional areas: behavior related to breathing, eating, and drinking; elimination patterns; personal hygiene behavior; rest and activity patterns; and patterns of solitude and social interaction. The aim is to maintain involvement in activities associated with positive moods and, if possible, to avoid situations that trigger depression.97 This approach has been effective at helping family members of terminally ill patients see and accept functional decline.

Alternative and Complementary Therapies. Complementary therapies may help reduce mild depressive symptoms, or they may be used as an adjunct to other therapies for more severe depressive symptoms.69 Strategies described for anxiety, such as guided imagery and visualization, the use of drawings or photographs, and music therapy, also may be used for depression. Art therapy for creative self-expression, use of humor and laughter, aerobic exercise, and aromatherapy massage have been helpful for mild depressive symptoms.68 Phototherapy, which is exposure to bright, wide-spectrum light, has shown promise in patients with cancer.68 See Chapter 25, Complementary and Alternative Therapies in Palliative Care, for a more in-depth review.

Conclusion

The psychosocial issues in persons facing life-threatening illness are influenced by individual, sociocultural, medical, and family factors. Most patients receiving palliative treatment and their families experience expected periods of emotional turmoil that occur at transition points, as is seen, for example, along the clinical course of cancer. Some patients experience anxiety and depressive disorders. This chapter has described the spectrum of anxiety and depressive symptoms during the palliative care trajectory; models of interaction useful for understanding the interaction of psychiatric and medical symptoms and for designing appropriate treatments; guidelines for referral to trained psychiatric clinicians; and a range of treatments for anxiety and depression. Supportive psychotherapeutic measures, such as those described in this chapter, should be used routinely because they minimize distress and enhance feelings of control and mastery over self and environment. Assessment and treatment of psychosocial problems, including physical symptoms, psychological distress, caregiver burden, and psychiatric disorders, can enhance quality of life throughout the palliative care trajectory.

This was reflected in Mrs. Brady’s outcome. Following clarification that she would be receiving chemotherapy to halt disease progression plus awareness that her reason for refusing was based on memories of her mother and, thus, assumptions about her own outcome, led the patient to reconsider and accept treatment recommendations. A low-dose anxiolytic was suggested for use at bedtime, which the patient received on a short-term basis. Mrs. Brady was still well at the 1-year follow-up.

Delirium, Confusion, and Agitation

Herein lies a paradox [delirium], a condition that is often reversible, yet is the hallmark of dying in most patients. The challenge for the clinician is to identify and treat the reversible underlying causes in a manner that is consistent with the overall goals of care.—P. Lawlor

Key Points
- Delirium, confusion, and agitation are common symptoms at the end of life and are extremely distressing to both patient and family.
- Identifying patients at risk of developing these symptoms can lead to early recognition and prompt treatment.
- The etiology of these symptoms is frequently multi-factorial; some causes are reversible and others not.
- Patient and family education regarding the reasons for these mental changes and how they will be managed is essential.

The human “living” experience will eventually tread the path toward the inevitable physical decline that accompanies age, disease, and death. Yet each individual’s dying experience is as unique as the life that he or she has lived. Many of the common threads that often create fear in the dying process are similar and include the fear of pain, the fear of loss, and the fear of losing control over one’s physical, emotional, and mental capacities. As nurses caring for those that are facing the end of their lives and their families, it is important that we understand how to empower both patients and families and how to reassure them that they will receive the care and support necessary to control symptoms at life’s end.

Unmanaged physical and psychiatric symptoms impact negatively upon the quality of life for each person and his or her family. To ensure optimal quality of life, prompt recognition, assessment, and intervention of all symptoms become crucial for the well-being of the patient living and dying from advanced disease. The patient is often faced with many stressors throughout the course of his or her illness, and the accompanying psychological distress experienced is as varied and individualized as the patient’s personality, coping ability, social support, and medical factors. Cognitive disorders are frequently seen in dying patients. For example, in the advanced cancer patient, delirium has been found to be the main reason for cognitive failure. This chapter specifically discusses the symptoms of delirium, confusion, agitation, and dementia and provides nurses with a framework for approaching patients with cognitive disorders in the palliative care setting.

Prevalence

The elderly, postoperative patients, critical care patients, and those facing the last days and hours of life are subject to alterations in cognition. Many patients develop psychiatric symptoms during the terminal phase of illness, either alone or in
combination with other physical symptoms. The varied psychiatric complications include anxiety, depression, and cognitive disorders. Cognitive disorders have a negative impact on patient functional capacity and often lead to a poor prognosis. Losing one’s sense of “self” is one of the most feared aspects of dying, and maintaining intellectual activity has been highlighted as an important area within the “good death” literature. A recent survey revealed that 92% of the seriously ill respondents identified mental awareness as an important aspect for a good death, while only 65% of their physicians viewed this as a priority. Maintaining a mental capacity facilitates the patient’s ability to strengthen his or her relationships with loved ones, and achieves a sense of control and the ability to complete life by resolving past issues and contributing to others. Clinically, observations focusing on global consciousness within several palliative care settings have identified that the percentages of “alert” patients often ranged from 25% to 82% during the final week of life. This decreased dramatically to 10% to 45% in the last 3 days of life, therefore, concluding that only 34% of these patients were able to “speak lucidly” before death.

Delirium is considered the most common cognitive disorder in the palliative care setting and is found in as many as 80% of patients with advanced cancer. Elderly and terminally ill cancer patients with pain are twice as likely to develop cognitive disorders, often a result of opioid use, than those without pain. Delirium has been reported in 24% to 40% of hospitalized patients evaluated by a psychiatric consultation. About 30% percent of patients in the intensive care unit (ICU) and 40% to 50% of elderly patients after hip replacement surgery have delirium. Up to 60% of elderly hospitalized patients develop delirium as a complication during their hospitalized course. A recent report indicated that 66% to 84% of elderly hospitalized patients with delirium are misdiagnosed. Many studies have reported the lack of detection and identification of delirium. These studies include many reasons for the lack of reporting delirious patients:

- Differing diagnostic terms or descriptors from clinician to clinician (vague descriptors such as confusion, agitation, acute brain syndrome, or metabolic encephalopathy)
- Varying presentations of delirium or fluctuations (hypoactive, hyperactive, etc.)
- Attributing cognitive changes to dementia, depression, or senescence
- Lack of baseline assessment using validated assessment tools
- Inexperienced clinicians

Some clinicians may consider delirium to be the “hallmark” of dying, or a metaphor for what is termed “terminal drop,” which distinguishes delirium for those who are actively dying. Its relevance to palliative care is evident. Delirium is also one of the most commonly encountered mental disorders in general hospital practice and has been referred to as “everyman’s psychosis,” which accounts for the fact that everybody is potentially susceptible. For patients who are actively dying, the metaphor of delirium might be used as an aid to diagnosis and to management, while keeping it distinct from the delirium encountered among those not recognized at the outskirts of dying. While delirium can occur at any age, the high incidence in elderly patients is often overlooked. Delirium has also been referred to as the “reversible madness,” which no clinician should overlook. Studies have indicated that approximately 30% to 67% of delirium episodes are reversible. Delirium is often unrecognized early in its onset, when manifestations are mild and easily treated. Failure to recognize this symptom and provide early management contributes not only to significant morbidity and mortality but also to an underestimation of its prevalence. Therefore, early detection and assessment are likely to improve patient quality of life. Objective monitoring and a high level of clinical awareness and skill are necessary to detect and treat cognitive symptoms within the palliative setting.

Definition (Terminology of Cognitive Changes)

Understanding the many symptoms, syndromes, and diagnoses associated with cognitive changes in persons with an advanced illness can be difficult at best, and the use of these definitions is often inconsistent in both clinical practice and the nursing and medical literature. “Confusion,” for example, may at times be used to describe a symptom; at other times, “confusion” may be used to describe a syndrome. Terms such as “encephalopathy” and “acute confusional state” are often used to describe changes in mental status instead of using a psychiatric classification based upon set criteria from the DSM-IV. Delirium, for example, may also be referred to as an acute confusional state, acute brain syndrome, and/or an acute organic reaction. In addition, many of these are complex disorders having overlapping yet distinct etiologies and clinical characteristics. Cognitive disorders in the medically ill interface between medicine and psychiatry and all too often owned by neither. The use of imprecise terminology can lead to mislabeling of behaviors, miscommunication among health care professionals, and misdiagnoses of cognitive changes. Therefore, the potential for the mismanagement of any cognitive change is extremely high.

Symptoms Associated with Cognitive Changes

The various labels used to categorize cognitive changes are based on the observation and evaluation of symptoms and behaviors. A common language regarding these symptoms is essential for accurate communication among health care professionals, which can decrease the variabilities often seen in caring for patients with reversible symptoms (i.e., delirium).
Anxiety

A least change in cognition can lead to anxiety. Cognitive impairment, regardless of the underlying cause, can disrupt both the receiving and the processing of sensory information. This results in a diminished ability to handle stressful situations and can contribute to the sensation of anxiety. Anxiety may be described as a fear of the unknown (not knowing what is expected) or fear of the known (knowing what to expect), and is considered a universal human experience. Factors contributing to anxiety may include previous or underlying anxiety disorders, unmanaged pain, and associated medical factors (metabolic abnormalities, medication side effects, and withdrawal states). Anxious patients may complain of tension, restlessness, jitteriness, autonomic hyperactivity, vigilance, insomnia, distractibility, shortness of breath, numbness, apprehension, and worry or rumination. However, the patient will most often present with a chief complaint identifying the somatization of anxiety that, therefore, is often overshadowed with a physical complaint. The assumption that anxiety is a normal companion to the terminal phase is not considered helpful to both the assessment and the interventions associated with this symptom.

There are multiple factors that can contribute to anxiety in the terminal setting. Many studies have identified a higher prevalence of anxiety when combined with depression. Patients with anxiety often have multiple etiologies, and the clinician should not exclude psychological and existential issues as contributory factors, particularly in the alert and oriented patient.

Confusion

Confusion is common among terminally ill patients and has broad consequences for their care and well-being. A recent study that highlighted nurse-identified confusion in 299 hospice patients compared confused patients with nonconfused patients. The median age of patients studied was 78 years, and there was an incidence of malignancy in 54%. The data identified 56% of the patients as confused the week before assessment, and of those patients, 36% were severely confused or disabled by confusion. Compared with the nonconfused patients, the confused patients were more likely to have cancer (64% vs. 43%) and to live in the long-term care setting (21% vs. 33%). Of these patients, common manifestations included disorientation to time and place, impaired short-term memory, drowsiness, and easy distractibility. From this data, inappropriate mood, a cancer diagnosis, agitation, and age were considered variables that predicted problematic confusion.

Acute confusion or delirium is a manifestation of compromised brain function and has been identified as the most frequently occurring cognitive disorder in the elderly. The American Psychiatric Association (APA) (2000) defines acute confusion as a syndrome that is characterized by a disturbance of consciousness and changes in cognition that develop abruptly (over a short period of time). If untreated, acute confusion in the elderly patient can contribute to excessive disability, morbidity, and mortality.

Incidence rates of acute confusion in the elderly hospitalized patient range from 33% to 80%, with an estimated mean at 40%. However, the assessment and effective management for confused elderly hospitalized patients is problematic, and it is predicted that as many as 7 of 10 older patients who experience acute confusion will not receive an accurate diagnosis, thereby contributing to poor management.

Several older studies have laid the groundwork to help clinicians understand the various etiologies and risk factors associated with the diagnosis of confusion, which include the following work and associated factors:

- Foreman (1992): low potassium, elevated glucose, elevated sodium, elevated blood urea nitrogen/creatinine ratio
- Inouye, Viscoli, Horwitz, Hurse, & Tinetti (1993): vision impairment, severity of illness, cognitive impairment, high blood urea nitrogen, and creatinine ratios
- Pompei, Foreman, Rudberg, Inouye, Brand, & Cassell (1994): cognitive impairment, burden of comorbidity, depression, and alcoholism
- Inouye & Charpentier (1996): malnutrition, three new medications, internal bladder catheter, an iatrogenic event, use of physical restraints

Other contributing factors associated with the onset of acute confusion identified in long-term care residents include a diagnosis of dementia, polypharmacy, fluid and electrolyte imbalances, metabolic disturbances, sensory impairment, and multiple disease processes.

Agitation

Agitation has been used to describe specific behaviors, syndromes, and outcomes of multiple psychiatric or medical etiologies. Allen has described agitation as being better understood as a group of symptoms that might characterize an underlying disorder. Agitation can include many different behaviors or manifestations including anxiety, aimless wandering, pacing, cursing, screaming, calling out to a passerby, and arguing. In a factor analysis of agitated behaviors, Cohen-Mansfield and Billing identified four types of agitation:

1. Physically aggressive behaviors: hitting, kicking, tearing, pushing, and cursing
2. Physically nonaggressive behaviors: pacing, inappropriate robing or disrobing, repetitive mannerism, and handling things inappropriately
3. Verbally agitated behaviors: constant request for attention, screaming, complaining, and negativism
4. Hiding/hoarding behaviors

These researchers further identified correlations between medical diagnoses and types of agitated behavior. They noted that nursing home residents who typically manifest agitation...
through physical behaviors usually suffer from dementia but are not otherwise generally ill. Verbal agitation was found to be prevalent in persons with a generally ill condition and in persons with unrelieved pain. However, verbal agitation was not associated with dementia. The researchers believed that the correlation of verbal agitation with disease and pain might be explained by the possibility that agitation is a form of expression of suffering from a medical disorder. This study illustrates the importance of describing the agitated behaviors and not necessarily describing the patient as being agitated.39

Other researchers have also noted a relationship between disease progression and specific agitated behaviors. Persons with dementia, for example, often exhibit agitation.40,41 This is most likely a direct result of brain alterations that contribute to impairments in memory, judgment, and impulse control. Agitation may be a person’s attempt to express feelings and needs that cannot be verbalized, either physical or emotional (pain, dyspnea, or frustration).39

**Delirium**

Delirium is a complex psychiatric syndrome and has attracted growing attention in the medical and nursing literature. Descriptions of delirium can be found in medical writings from 2300 years ago to the present.40 In spite of this history, the terms used to describe the syndrome have been inconsistent, overlapping, poorly defined, and often related to the discipline or specialty observing the condition. Historically, terms such as organic brain syndrome, acute secondary psychosis, exogenous psychosis, and sundown syndrome have been used to describe delirium.41 A review of the recent literature reveals a continuing use of a variety of terms to characterize delirium, including acute brain failure, acute confusional state, terminal restlessness/agitation, and ICU psychosis.29,42–45 The APA first used the term “delirium” to describe the syndrome, and established diagnostic criteria in the third edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-III), published in 1980.40 These criteria were revised in the DSM-III-R and DSM-IV. While diagnostic criteria in the earlier editions were developed from the opinions of committees of experts, the latest edition (DSM-IV) published in 1994, relied on comprehensive review of the literature and data from prospective studies of delirium.47

Based on the DSM-IV criteria, delirium may be defined as an acute and fluctuating organic brain syndrome characterized by global cerebral dysfunction that includes disturbances in attention, the level of consciousness, and basic cognitive functions (thinking, perception, and memory).20 Other features commonly associated with delirium include increased or decreased psychomotor activity, disturbances in the sleep-wake cycle, and emotional lability.41

The diagnosis of delirium is primarily clinical, based upon careful observation and awareness of key features.40,47 Because the signs and symptoms are nonspecific, the clinician must look for a constellation of findings (subtle change or disturbance in consciousness and/or a change in cognition), identify the rapidity of onset, and assess for associated medical and environmental risks that lead to a definitive diagnosis. Delirium is frequently unrecognized and misdiagnosed by clinicians.40 The fact that demented, depressed, and anxious patients may develop delirium additionally makes the diagnosis difficult.40 However, because of delirium’s prevalence in the hospitalized elderly, the ICU, cancer patients, and the terminally ill, any patient with deterioration in mental status is best presumed to be delirious until it is proved otherwise.13,32,50,51 The distinguishing characteristics of delirium and dementia are outlined in Table 20–1.

An understanding of delirium, both its clinical course and its assessment, is particularly important for the palliative care nurse. The palliative care patient population has a high prevalence of commonly identified risk factors for delirium that include advanced age, dementia/cognitive impairment, severe medical illness and the use of multiple medications (sedative/hypnotics, anticholinergics, corticosteroids, and opioids).34,52–54 Furthermore, the consequences of delirium can be severe for both patients and caregivers. The presence of delirium is associated with increased mortality and morbidity, including prolonged hospital stays, functional decline, long-term care placement, and, in the case of the imminently dying, a distressing and uncomfortable death.39,55–58 In addition to medical morbidity, there is evidence that psychosocial morbidity is also significant. A significant number of patients who recover from delirium remember the episode and report distress from the experience that includes anxiety, helplessness, and fear.59–62 Caring for patients with hyperactive delirium has obvious stressors for both families and nurses; however, hypoactive delirium is also stressful, especially for families who regret premature separation from a patient who can no longer communicate.67 Delirium robs patients and families of valuable time.

Because of the subtle presentation of symptoms and fluctuating course associated with delirium, nurses, who have more frequent and continuous contact with patients, are key to the early recognition of delirium.20 However, research during the past decade continues to show that nurses fail to recognize delirium when it is present, especially in its hypoactive forms.62 This is partly due to assessments of cognitive status that rely primarily on orientation, to the exclusion of other aspects such as memory, attention, and perception.28,60,64 Useful tools have been developed to evaluate cognitive status and screen for delirium in patients in a variety of settings (hospital, home, long-term care, ICU). These tools are reviewed later in this chapter. Consistent use could improve early recognition of delirium by nurses.65,66 However, to better understand the manifestations of delirium, it may be helpful to discuss each diagnostic criterion in more detail.

**Disturbance of Consciousness.** The term “disturbance of consciousness,” while inherently vague, is a critical feature in delirium.67 Disturbance of consciousness refers to impairments in attention and the ability to be aware of and sustain attention to the environment. Attention is typically fluctuating and may present as a change in the level of consciousness, slowed or inadequate reactions to stimuli or the environment, and easy distractibility. Due to this distractibility, individuals may be
Delirium, Confusion, and Agitation

Delirium, Confusion, and Agitation

405

unable to follow conversations or complete simple tasks.68 For example, patients may be slow to respond, unable to maintain eye contact, or may fall asleep between stimuli. Increasing stimuli (touch, sound) may be needed to elicit a response. Conversely, patients may be hyperalert and over-attentive to cues or objects in the environment.69 The ability to focus can be assessed by the patient's inability to complete a particular task such as spelling "world" backwards, or subtracting serial 7s.67

Change in Cognition. Many aspects of cognitive function are impaired in delirium, including orientation, memory, language, thinking, and perception.57,68 Disorientation usually manifests as disorientation to time or place, with time disorientation being the first to be affected. Disorientation to other people commonly occurs, but disorientation to self is very rare.68 Short-term memory deficits are the most evident memory impairments. Patients may not remember conversations, television shows, or verbal instructions. They may have no recollection of the conversation or remember only bits and pieces. For example, the person experiencing cognitive changes may remember the nurse visiting but not anything the nurse said or did. Language disturbances associated with delirium range from a lack of fluency and spontaneity to rambling discourse that switches from topic to topic. The content of language may be rich in imagery or extremely simple. There may be long pauses in the conversation or use of repetitious phrases by the patient. The person experiencing delirium may also have difficulty finding the correct word to use in conversation or naming objects (anomia). Thinking is usually disorganized, as evidenced by incoherent speech, deficits in logic, and responses that are irrelevant to questions asked.57,69 Perceptual disturbances may include misinterpretations, illusions, or hallucinations. misperceptions and hallucinations are most common, but auditory, tactile, gustatory, and olfactory misperceptions or hallucinations can also occur. The individual with delirium may have the delusional conviction that the hallucination is real and exhibit emotional and behavioral responses consistent with the hallucination’s content.

Addition Features of Delirium. Although not required for the diagnosis of delirium, other features, including sleep–wake disturbances, psychomotor activity changes, and emotional lability, often accompany delirium. It is helpful to assess for these symptoms and monitor for any changes in these over time. Disturbance in sleep patterns is frequently observed in persons with delirium and was one of the criteria for delirium in the DSM-IIIR (3rd ed., revised) definition. However, this criterion was excluded from the DSM-IV definition because it lacked specificity. It is common to observe daytime sleepiness, nighttime agitation, and disturbances in sleep continuity in addition to other features of delirium.

Persons with delirium may also exhibit disturbed psychomotor activity. Continuing research has indicated that there are several subtypes based on motor activity of delirium. These include a hyperactive/hyperalert subtype, a hypoactive/hypoalert subtype, and a mixed subtype that features components of the other two (Table 20–2). According to this description, hyperactive/hyperalert patients are restless, agitated, with overactivity of the sympathetic nervous system. Clinicians expect delirium to present with agitation, hallucinations, and inappropriate behavior. Indeed, the hyperalert–hyperactive variant of delirium is most commonly recognized. Characteristics of hyperactive–hyperalert delirium include plucking at bedclothes, wandering, verbal or physical aggression, and increased alertness to stimuli, psychosis, and mood lability.

Hypoactive/hypoalert patients appear lethargic and drowsy, respond slowly to questions, and do not initiate movement. This type of delirium is characterized by withdrawal from people and usual activities and decreased responsiveness to stimuli. Because these patients are quiet and withdrawn, the delirium is often overlooked or attributed to dementia, depression, or senescence. Differentiating delirium from the normal aging process, dementia, or depression requires careful and repeated assessment.

A patient with a mixed subtype shows alternating periods of both types of behavior. Clinicians are likely to recognize the delirium only during periods of agitation, combativeness, or perceptual disturbance. Periods of lethargy may be seen as clinical improvements, when, in fact, the delirium may be continuing and increasing in severity. A complete assessment of all symptoms of delirium is required before a change in behavior can be labeled as an improvement.

Persons with delirium may exhibit emotional disturbances. Anxiety, fear, depression, irritability, anger, euphoria, and apathy are common, with anxiety being the prevailing emotion. The delirious patient may be emotionally labile, rapidly and unpredictably shifting from one emotional state to another.

### Differentiation of Delirium and Dementia

Dementia, in contrast to delirium, occurs in patients who are relatively alert and with little or no clouding of consciousness. Dementia differs

---

in its presence by occurring gradually and progressively over time and is not associated with an acute onset as noted in delirium. The sleep-wake cycle is not disrupted in dementia but significantly interferes with short-term memory loss, while long-term memory remains intact. Dementia has a pronounced impact upon judgment and abstract thinking and is associated with disturbances in higher cortical functions (apraxia, aphasia).

Dementia is a strong risk factor for the development of delirium. It has been noted in the elderly that up to two thirds of cases of delirium are superimposed on dementia. Many patients who have experienced delirium are slow to recover to their previous level of function and are at greater risk for developing dementia. The symptom profile of delirium is very similar in patients with and without dementia. Patients with dementia, however, tend to have more symptoms of delirium, especially psychomotor agitation/retardation, disorganized thinking, and disorientation. While some have postulated that hypoactive delirium is more prevalent in dementia, both subtypes have been identified.

Differentiating dementia from delirium is a challenge for clinicians. In one study, presence of dementia was found to be a significant risk factor for nurses’ nonrecognition of delirium. Careful observation and comprehensive history taking is essential to identify acute mental status changes in demented patients that may indicate a superimposed delirium. While both conditions share the features of impaired memory, thinking, and judgment, the features of acute onset, altered level of consciousness, and fluctuating course are specific for delirium. Likewise, psychotic symptoms and agitation are also common in both disorders. However, in dementia, the symptoms are consistent and generally do not wax and wane (see Table 20-2).

**Assessment**

As discussed above, delirium is often unrecognized and misdiagnosed by clinicians. Factors contributing to under-diagnosis of acute confusion in the elderly include lack of formal training in gerontology, knowledge deficits about acute confusion, and lack of knowledge about the availability and use of established, standardized instruments to assess changes in cognition. It is likely similar factors contribute to inadequate recognition of delirium in the palliative care setting. A number of delirium assessment instruments have been developed for use in various populations. These tools vary in the goals, type of data collected, qualifications required of rater, number of items, and time required to complete. Some are burdensome and difficult to use in daily clinical practice. Palliative care nurses must identify persons at greatest risk for delirium and use standardized, reliable tools to assist in the diagnosis of delirium in daily practice.

**Predicting Delirium.** Knowledge of the risk factors associated with delirium is required to identify the population at greatest risk and to assist in early diagnosis. One model used in hospitalized elderly patients is the Risk Assessment Model for Delirium. Factors present on admission that are associated with the development of delirium during hospitalization are visual impairment, severe illness, dehydration, and previous cognitive impairment. Events associated with the onset of delirium during hospitalization (precipitating factors) include use of physical restraints, malnutrition, more than three medications added to the medication profile, and insertion of an indwelling catheter. Using this information, nurses can identify those elderly at greatest risk for delirium, intervene to prevent delirium, and initiate early treatment if delirium does occur.

Based on multiple studies on delirium, Sarhill and colleagues identified the following as predisposing factors for delirium in persons with advanced cancer: medications (opioids, steroids, metoclopramide, and phenothiazine), age 65 and older, brain metastasis, infection, hypoxia, dehydration, hypercalcemia, anemia, and renal failure. Persons were more likely to develop delirium if five or more of these predisposing factors were present, with each medication considered a separate factor. Identification of these risk factors alerts the palliative care nurse to those patients who require a more detailed assessment for early identification of delirium.

**Delirium Assessment Instruments.** The Mini-Mental State Examination (MMSE) provides a systematic, scored method for evaluating cognitive function. This scored examination can indicate early changes in cognition as it relates to the cortical function of the brain. Orientation, attention, recall, and language are evaluated. Scores below 24 (out of a maximum of 30) are indicative of cognitive changes. The MMSE is intended to measure cognitive change over time, but does not differentiate among delirium, dementia, anxiety, and depression. Thus, the MMSE may best be used as a predictive instrument that directs the clinician to use a delirium assessment instrument for additional information.

Table 20-3 provides an overview of instruments used to assess delirium. These instruments are reviewed because they distinguish delirium from dementia and assess at least several of the multiple features of delirium. While all of these instruments require further study to determine application across varied settings and among different patient populations, the following have shown good reliability and validity in identifying delirium in selected populations.

- The Memorial Delirium Assessment Scale (MDAS) (Figure 20-1) is based on the DSM-IV criteria and is psychometrically valid and reliable in palliative care settings. The MDAS requires minimal training for use and is appropriate for both clinical practice and research.
- The Delirium Rating Scale (DRS) is the most widely used assessment instrument based on the DSM-III criteria and is useful in the assessment of delirium in the terminally ill. It also has the best results for screening symptom severity. However, it lacks administrative ease for the clinician, and no publications are available on the use of the DRS by nurses.
The Confusion Assessment Method (CAM) is designed for use by a trained interviewer to assess cognitive functioning in elderly patients on a daily scheduled basis. Despite its attempt to streamline a diagnosis, the CAM is a complex instrument that requires extensive instruction for the rater due to its subtleties.

Nurses designed the NEECHAM Confusion Scale (NCS) to use in routine assessments of hospitalized elderly. No published studies in the palliative care setting are found.

The Bedside Confusion Scale (BCS) (Table 20–4) correlates with the CAM and is designed for use in the palliative care setting. It requires minimal training and only about 2 minutes to complete.

Delirium assessment protocols in hospitalized elderly and palliative care patients may include daily or even every-shift evaluations for delirium. Given the prevalence of delirium in these settings, this frequency makes sense. There are no published recommendations on the frequency with which delirium assessment tools should be used in outpatient and home care settings, although some of these patients may be at as great a risk as those in inpatient settings. Too frequent evaluation for delirium in persons at low risk for delirium is burdensome to both the patient and the clinician. It does make sense to complete a baseline evaluation on all patients and then base the frequency of follow-up assessments on the number of risk factors for delirium present.

### Factors Contributing to Delirium

There are numerous factors that can contribute to cognitive changes in the palliative setting. Multiple medications and more predominantly, the use of polypharmacy (using more than one drug from the same class) can contribute to delirium. Accumulation of specific medications and their metabolites can be seen especially from drugs coming from the benzodiazepines, anticholinergics, opioid analgesics, etc. Other contributing causes include organ failure, for example patients who have end-stage liver failure are unable to effectively manage the metabolism of medications that undergo hepatic oxidation (e.g. benzodiazepines). Therefore, to summarize, common underlying medical conditions that contribute to delirium include:

- Medication toxicities, especially noted in the use of anticholinergic agents, anticonvulsants, anti-parkinsonism agents, corticosteroids, cimetidine, opioids, sedatives, alcohol, and illicit drugs
- Withdrawal from alcohol, sedatives, benzodiazepines, and barbiturates

MDAS, Memorial Delirium Assessment Scale; DRS, Delirium Rating Scale; CAM, Confusion Assessment Method; NCS, NEECHAM Confusion Scale; BCS, Bedside Confusion Scale
**INSTRUCTIONS:** Rate the severity of the following symptoms of delirium based on current interaction with subject or assessment of his/her behavior or experience over past several hours (as indicated in each time.)

**ITEM 1—REDUCED LEVEL OF CONSCIOUSNESS** (AWARENESS): Rate the patient’s current awareness of and interaction with the environment (interviewer, other people/objects in the room; for example, ask patients to describe their surroundings).

- **0**: none
  - (patient is largely unaware of elements in the environment or not spontaneously interacting)

- **1**: mild
  - (patient is aware of some elements in the environment and interacts appropriately)

- **2**: moderate
  - (patient is unaware of some or all elements in the environment, or not spontaneously interacting with the interviewer; becomes incompletely aware and inappropriate interactive when prodded strongly; interview is prolonged but not seriously disrupted)

- **3**: severe
  - (patient is unaware of all elements in the environment with no spontaneous interaction or awareness of the interviewer, so that the interview is difficult-to-impossible, even with maximal prodding)

**ITEM 2—DISORIENTATION:** Rate current state by asking the following 10 orientation items: date, month, day, year, season, floor, name of hospital, city state, and country.

- **0**: none
  - (patient knows 9–10 items)

- **1**: mild
  - (patient knows 7–8 items)

- **2**: moderate
  - (patient knows 5–6 items)

- **3**: severe
  - (patient knows no more than 4 items)

**ITEM 3—SHORT-TERM MEMORY IMPAIRMENT:** Rate current state by using repetition and delayed recall of 3 words [patient must immediately repeat and recall words 5 min later after an intervening task. Use alternate sets of 3 words for successive evaluations (for example, apple, table, tomorrow; sky, cigar, justice)].

- **0**: none
  - (all 3 words repeated and recalled)

- **1**: mild
  - (all 3 repeated, patient fails to recall 1)

- **2**: moderate
  - (all 3 repeated, patient fails to recall 2, 3)

- **3**: severe
  - (patient fails to recall 1 or more words)

**ITEM 4—IMPAIRED DIGIT SPAN:** Rate current performance by asking subjects to repeat first 3, 4, then 5 digits forward and then 3, then 4 backwards; continue to the next step only if patient succeeds at the previous one.

- **0**: none
  - (patient can do at least 5 numbers forward and 4 backward)

- **1**: mild
  - (patient can do at least 5 numbers forward, 3 backward)

- **2**: moderate
  - (patient can do 4–5 numbers forward, cannot do 3 backward)

- **3**: severe
  - (patient can do no more than 3 numbers forward)

**ITEM 5—REDUCED ABILITY TO MAINTAIN AND SHIFT ATTENTION:** As indicated during the interview by questions needing to be rephrased and/or repeated because patient’s attention wanders, patient loses track, patient is distracted by outside stimuli or over-absorbed in a task.

- **0**: none
  - (none of the above; patient maintains and shifts attention normally)

- **1**: mild
  - (above attentional problems occur once or twice without prolonging the interview)

- **2**: moderate
  - (above attentional problems occur often, prolonging the interview without seriously disrupting it)

- **3**: severe
  - (above attentional problems occur constantly, disrupting and making the interview difficult-to-impossible)

**ITEM 6—DISORGANIZED THINKING:** As indicated during the interview by rambling, irrelevant, or incoherent speech, or by tangential, circumstantial, or faulty reasoning. Ask patient a somewhat complex question (for example, “Describe your current medical condition.”).

- **0**: none
  - (patient’s speech is coherent and goal-directed)

- **1**: mild
  - (patient’s speech is slightly difficult to follow; responses to questions are slightly off target but not so much as to prolong the interview)

- **2**: moderate
  - (disorganized thoughts or speech are clearly present, such that interview is prolonged but not disrupted)

- **3**: severe
  - (examination is very difficult or impossible due to disorganized thinking or speech)

*(continued)*
Symptom Assessment and Management

**ITEM 7—PERCEPTUAL DISTURBANCE:** Misperceptions, illusions, hallucinations inferred from inappropriate behavior during the interview or admitted by subject, as well as those elicited from nurse/family/chart accounts of the past several hours or of the time since last examination:

- **0: none** (no misperceptions, illusions, or hallucinations)
- **1: mild** (misperceptions or illusions related to sleep, fleeting hallucinations on 1–2 occasions without inappropriate behavior)
- **2: moderate** (hallucinations or frequent illusions on several occasions with minimal inappropriate behavior that does not disrupt the interview)
- **3: severe** (frequent or intense illusions or hallucinations with persistent inappropriate behavior that disrupts the interview or interferes with medical care)

**ITEM 8—DELUSIONS:** Rate delusions inferred from inappropriate behavior during the interview or admitted by the patient, as well as delusions elicited from nurse/family/chart accounts of the past several hours or of the time since the previous examination.

- **0: none** (no evidence of misinterpretations or delusions)
- **1: mild** (misinterpretations or suspiciousness without clear delusional ideas or inappropriate behavior)
- **2: moderate** (delusions admitted by the patient or evidenced by his/her behavior that do not or only marginally disrupt the interview or interfere with medical care)
- **3: severe** (persistent and/or intense delusions resulting in inappropriate behavior, disrupting the interview or seriously interfering with medical care)

**ITEM 9—DECREASED OR INCREASED PSYCHOMOTOR ACTIVITY:** Rate activity over past several hours, as well as activity during interview, by circling (a) hypoactive, (b) hyperactive, or (c) elements of both present.

- **0: none** (normal psychomotor activity)
- **a b c** (Hypoactivity is barely noticeable, expressed as slightly slowing of movement. Hyperactivity is barely noticeable or appears as simple restlessness.)
- **a b** (Hypoactivity is undeniably, with marked reduction in the number of movements or marked slowness of movement; subject rarely spontaneously moves or speaks. Hyperactivity is undeniable, subject moves almost constantly; in both cases, exam is prolonged as a consequence.)
- **a b c** (Hypoactivity is severe; patient does not move or speak without prodding or is catatonic. Hyperactivity is severe; patient is constantly moving, overreacts to stimuli, requires surveillance and/or restraint; getting through the exam is difficult or impossible.)

**ITEM 10—SLEEP-WAKE CYCLE DISTURBANCE (DISORDER OF AROUSAL):** Rate patient’s ability to either sleep or stay awake at the appropriate times. Utilize direct observation during the interview, as well as reports from nurses, family, patient, or chart describing sleep-wake cycle disturbance over the past several hours or since last examination. Use observations of the previous night for morning evaluations only.

- **0: none** (at night, sleeps well; during the day, has no trouble staying awake)
- **1: mild** (mild deviation from appropriate sleepfulness and wakefulness states: at night, difficulty falling asleep or transient night awakenings, needs medication to sleep well; during the day, reports periods of drowsiness or, during the interview, is drowsy but can easily fully awaken him/herself)
- **2: moderate** (moderate deviations from appropriate sleepfulness and wakefulness states: at night, repeated and prolonged night awakening; during the day, reports of frequent and prolonged nappling or, during the interview, can only be roused to complete wakefulness by strong stimuli)
- **3: severe** (severe deviations from appropriate sleepfulness and wakefulness states: at night, sleeplessness; during the day, patient spends most of the time sleeping or, during the interview, cannot be roused to full wakefulness by any stimuli)

**Figure 20-1.** (Continued)

- Metabolic abnormalities that include hypoglycemia, organ failure (hepatic, renal, pulmonary), fluid and electrolyte imbalances, and endocrinopathies (hypothyroidism, hyperparathyroidism)
- Systemic infections
- Head trauma
- Neoplastic disease
- Vascular disorders (transient ischemic attack, thrombosis, myocardial infarction, cardiac failure)\(^\text{19,21}\)

**Dehydration**

People with chronic illness and the elderly are at risk for fluid deficits due to a number of causes, including use of medications (diuretics), infections/fever, and inadequate fluid intake. Fluid deficits, whether they are volume depletion (intravascular water and electrolytes) or dehydration (total body water deficit), place patients at risk for numerous adverse consequences, including changes in behavior, cognition, and energy level.\(^\text{82}\) Dehydration can cause confusion,
restlessness, and neuromuscular irritability. On the other hand, reduced intravascular volume and glomerular filtration are known to precipitate prerenal failure. The subsequent accumulation of drugs normally excreted by the kidneys may precipitate further adverse effects. Fluid deficits can also increase the risk of pressure sores, precipitate fatigue, fever, constipation, and postural hypotension. Furthermore, dehydration has been identified as a risk factor for delirium.32,53

In patients whose death is not imminent, correction of fluid deficits is imperative. However, fluid replacement for patients approaching death is controversial. In most care settings, aggressive maintenance of fluid and electrolyte balance is common practice. Yet some palliative care practitioners argue against the appropriateness of fluid replacement in the last days of life. Common arguments concerning the benefits of not correcting fluid deficits include: (a) decreased stress on the pulmonary system; (b) decreased brain swelling and discomfort related to headaches and confusion; (c) reduction in cardiopulmonary problems (congestive heart failure, pulmonary edema); (d) decreased airway secretions; (e) reduction in urinary incontinence with decreased urine output; and (f) decrease in pain from the potential release of endorphins. On the other hand, some palliative care providers have challenged the idea that dehydration is universally beneficial in dying patients. The potential burdens of fluid deficit include: (a) precipitation of confusion, restlessness, or neuromuscular irritability from buildup of toxins and metabolites; (b) confusion and syncope when dehydration is rapid (diarrhea, paracentesis); (c) discomfot symptoms such as thirst, dry mouth, cracked, parched or painful oral mucosa; and (d) the lay perspective of dehydration as contributing to an uncomfortable death.

There is no evidence from randomized controlled trials to support approaches to fluid deficits in terminally ill patients. Thus, we do not know the benefits and risks of fluid deficit or whether hydration really can improve symptoms, quality of life, or quantity of life when used in a situation in which the patient likely has a life expectancy that might be measured in days as opposed to months. In their absence, current opinion on the benefits and risks of terminal dehydration rests primarily on clinical observation and descriptive studies conducted in the last decade. These studies primarily involved patients with late stage, terminal cancer and, therefore, findings may not be pertinent to other populations. They do, however, provide beginning insight into the experience of fluid deficit. For example, the distress experienced by dehydrated patients appears to be minimal. Other studies have shown that patients who are clinically dehydrated may have normal laboratory parameters. While experience of thirst and dry mouth has been found to be related to dehydration and hyperosmolality, others have found little relationship between fluid status and fluid therapy.

For patients in distress from neurotoxicity or thirst, a time-limited trial of hydration via carefully monitored intravenous fluids may be in order.31,106 Since dehydration most likely has an interactive effect on development of delirium, rehydration may or may not affect the course of delirium in the terminal phase.

It is possible that clinicians may provide comfort for dying patients by either avoiding or providing artificial hydration in the dying days. Decisions of hydration should be based on careful patient assessment and the goals of the individual patient and family. The decision to avoid artificial hydration in favor of oral fluids and meticulous oral hygiene may avoid problems such as pulmonary edema and intrusive technology. For patients in distress from neurotoxicity or thirst, a time-limited trial of hydration via carefully monitored intravenous (IV) or subcutaneous fluid administration may provide relief and promote comfort.

### Pharmacological Interventions for the Management of Delirium

The APA has developed a practice guideline to support the management of patients diagnosed with delirium. After a complete history and physical examination and discerning reversible contributing factors to delirium, a prompt psychiatric consultation should always be considered in the primary management for this patient population. Psychiatry may be able to point out important environmental factors that the primary care team has not considered, such as an increase or decrease in sensory input or opportunities that would improve orientation. Despite the conciseness and comprehensiveness of these guidelines, there is little information on the safety and efficacy of the newer antipsychotic that will be briefly described below.

Understanding that the use of sedative hypnotics (e.g., benzodiazepines) can actually contribute to the symptom of

delirium, a recent physician survey identified the lack of knowledge and skills in successfully treating delirium. The impetus for this survey was based upon the concerns that benzodiazepines were too commonly prescribed for the management of general delirium in older hospitalized patients. There is a substantial body of literature that can guide clinicians in the management of delirious medically ill older patients, who constitute the highest risk of developing this symptom. The APA clearly articulates that there is substantial clinical confidence and available data suggesting that the use of benzodiazepines as monotherapy may be ineffective in the treatment of delirium, with the exception, however, of those patients who are experiencing delirium as a result of withdrawal from alcohol or benzodiazepines. The physician survey was mailed to physicians thought to have experience caring for older patients who would at some point experience delirium in the course of their illness. A total of 286 surveys were collected to discern the clinical management of delirium.

The APA's consensus is that benzodiazepines have proven ineffective in the treatment of delirium. The APA further suggests that the use of benzodiazepines used in combination with haloperidol should only be considered for patients who cannot tolerate low doses of antipsychotic medications or for those with problematic anxiety or agitation.

The adverse effects of benzodiazepines are well documented in the delirium literature and include profound sedation, respiratory depression, and hypoxia. Benzodiazepines have been shown to contribute to troubling behavioral side effects such as anger, agitation, restlessness, hostility, and violent and aggressive behaviors. The rationale for choosing to use a benzodiazepine for the delirious patient outside of alcohol or benzodiazepine withdrawal should be clearly defined. Since benzodiazepines contribute to and worsen the symptom of delirium, they may be considered for use in patients who are extremely agitated or anxious and require sedation.

Haloperidol is most often considered as the drug of choice in the management of delirium with the exception of alcohol or benzodiazepine withdrawal. Haloperidol has very few anticholinergic side effects, has limited active metabolites, and is not as sedating as benzodiazepines. It is readily available for oral, intramuscular, subcutaneous, and IV administration (the latter two are not FDA approved in the United States and United Kingdom).

Haloperidol should be dosed at 1 to 2 mg every 2 to 4 hours as needed, with dose increases for agitated patients. Haloperidol can, however, prolong the QT interval and may require that patients be monitored if receiving IV dosing. Because most dopamine antagonist's antipsychotics are effective in the treatment of delirium, using the newer atypical antipsychotics may be considered. However, there are currently few randomized and controlled studies to promote strong evidence, but there is a need to investigate this area further.

Risperidone is widely accepted for use in elderly agitated and aggressive demented patients, with doses ranging from 0.5 mg to 1.5 to 2 mg/day for dementia patients and lower doses in delirious patients. In the literature, there have been a few case reviews that demonstrate the effectiveness of risperidone on delirium. Though the evidence is limited, it appears that risperidone could be used to effectively manage the psychotic symptoms often associated in the setting of delirium.

Olanzapine has been useful in a series of anecdotal case reports. It does not create extrapyramidal effects and is often considered as a second-line agent in patients who cannot tolerate the extrapyramidal effects of haloperidol. Olanzapine is initiated at 5 mg at bedtime and may be increased to 10 mg, with 2.5 mg as needed throughout the day.

Clinicians prescribing antipsychotics for delirium should have a basic knowledge of the drug interactions with other concomitant medications that the patient may encounter. For example, haloperidol, which is metabolized through the P450 enzyme system, inhibits the specific isoenzyme CYP 2D6 when combined with analgesics such as codeine or oxycodone. Haloperidol when combined with SSRIs (serotonin reuptake inhibitors) and TCAs (tricyclic antidepressants) can interfere with the metabolism of haloperidol.

Nonpharmacological Nursing Interventions

Delirium Risk Reduction. Given the correlation between the number of predisposing factors and the incidence of delirium, it makes sense to intervene promptly to reduce the number of risk factors. Inouye and colleagues demonstrated that the rate of delirium in elderly patients receiving multicomponent, targeted interventions to reduce risk factors was significantly lower than in those receiving usual care. The protocol included providing orientation communication tools, engaging patients in cognitively stimulating activities, promoting ambulation or active range of motion, administering a nonpharmacological sleep protocol if patient has difficulty falling asleep, using or repairing visual and hearing aids as needed, and instituting volume repletion in the presence of hydration. These interventions were most effective in patients who were at intermediate risk for delirium. The interventions had no significant effect on the severity of delirium once an episode had occurred, demonstrating that primary prevention is the most effective strategy. Although no similar studies are found in the palliative care setting, these should be part of basic nursing care for all patients, and most can be taught to patients' caregivers.

Restful Environment. In the presence of delirium, the interventions such as orientation and ambulation may no longer be as helpful. A quiet, restful environment is a means of reducing the internal and external sensory stimuli that often insult the delirious patient's cortical brain. Familiar sounds, smells, and textures convey warmth and caring for the agitation and restless patient. Patients who experience confusion as a result of a delirious episode may have a greater need to relate to the familiar voice of a significant caregiver or to the soft touch of a favorite pet. Since the visual field may present distorted images, sound, smell, and touch are avenues that nurses and caregivers can use to communicate understanding and reassurance for the cognitively impaired patient. Reorienting to time is of minimal value as time has little meaning to the patient. Television and extraneous noise should be avoided. By reducing the excess stimuli, pertinent relaxing sounds of music or a familiar voice can be received.

The sound of familiar music can also quiet the restless mind. Learning from the family or caregiver what the patient's favorite music has been in the past and encouraging its use not only includes the family but also promotes a soothing environment. When deemed appropriate by the professional support team, integrating the use of psalms and prayer may be of
value to the family whose background is influenced by the Judeo-Christian religions. Knowledge of rituals used in various cultures, along with individual/family belief systems, is essential.

Supportive Care for Terminal Agitation. The importance of supportive interventions for patients in the final hours of life and their family members should not be underestimated.\textsuperscript{10,121,122} It is important for the nurse to distinguish between acute confusion, signaling a possibly treatable and reversible delirium, and “nearing death awareness.” Callahan and Kelly\textsuperscript{123} define nearing death awareness as a special knowledge about the process of dying; it may reveal what dying is like and what is needed to die peacefully. Nurses have a unique role in helping caregivers understand this symbolic communication. Themes of nearing death awareness include describing a place, talking to or being in the presence of someone who is not alive, knowledge of when death will occur, choosing the time of death, needing reconciliation, preparing for travel or change, being held back, and symbolic dreams. When nurses understand these themes, what may sound like confused words to others may be understood as symbolic expressions of the patient’s own awareness that he or she is dying. For example, a plea of “I want to go home” may be answered with “I know, it’s time and you can go when you are ready,” rather than with the more literal “You are home.”\textsuperscript{124,125}

When the caregiver and nurse communicate compassionate understanding, the patient’s restlessness is often subdued.\textsuperscript{114,123,124} Caregivers can offer insight into the patient’s restlessness if queried on issues that may remain unresolved for the patient.\textsuperscript{120} Byock,\textsuperscript{125} identifies five requirements for relationship completion, by saying: “I forgive you”; “Forgive me”; “Thank you”; “I love you”; and “Goodbye.” Pain and resentment within the family that has been kept hidden during the patient’s illness may emerge when death is on the threshold. A counselor, chaplain, or other spiritual caregiver in the palliative care setting can offer families solace and support.

Use of Smell. The faint scent of freshly baked bread often conveys a sense of safety in one’s remote memory. A pleasant scent is remembered as a time of joy, a safe and secure moment of love and caring. The sense of smell travels by way of the olfactory nerve to the central part of the brain, known as the limbic system. The limbic system is known as the “seat of emotion,” where anxiety and fear are labeled as threatening to the self.\textsuperscript{14}

In palliative care settings throughout England and Ireland, scents are used as an intervention in the form of essential oils. Essential oils are aromatic substances extracted from plants.\textsuperscript{120,126} A minute drop of oil can be added to massage oil and applied to the skin in the form of a massage. Clinical studies have indicated a positive and prolonged effect in reducing anxiety when using scented oils in conjunction with massage.\textsuperscript{14,127} A review of clinical studies of patients in the palliative care setting concluded that providing massage with essential oil is of therapeutic benefit.\textsuperscript{127}

When patients experience the anxiety and fear associated with a delirious episode, a simple hand massage with lavender oil can help provide a calming and relaxing effect. The essential oil of lavender (\textit{Lavandula angustifolia}) acts primarily on the central nervous system, resulting in a sedative effect. The relaxation effect is believed to be a direct result of the biochemical properties of lavender due to its high content of linalyl acetate (ester). In the home setting, scented candles can be placed in the room. The use of candles can also symbolize a sacred space of solitude and peace.

Use of Touch. Touch with intent offered by the caregiver, nurse, or volunteer, may express caring and safety to the confused mind of the patient. The clinical experience of nurses using therapeutic touch has value in calming the patient who has reached the end of life’s journey. Therapeutic touch, a gentle and noninvasive expression by a nurse or caregiver, will relax the physical body, an effect that may be observed in the patient’s facial expression and relaxation of muscles as the breath ceases. Cathleen Fanslow-Brunjes,\textsuperscript{126} a nurse clinician who worked with Elisabeth Kübler-Ross and later at Calvary Hospital in the Bronx, pioneered the use of therapeutic touch while caring for the dying. The hand–heart connection developed by Fanslow-Brunjes\textsuperscript{126} is a relevant intervention for use in terminal restlessness and terminal anguish. Based on the principles of therapeutic touch, in conjunction with the ancient healing system of Tibetan Buddhism and Ayurvedic medicine, it encourages “letting go.”

Patient and Family Teaching

Patient and family education is the cornerstone of comprehensive end-of-life care. Through proper education and support, cognitive disorders may be avoided, recognized early, or shortened. When a cognitive disorder leads to distress, appropriate education and support can decrease the severity of symptoms by providing open and adequate communication to lessen the stimuli that exacerbate symptoms.\textsuperscript{128} Teaching activities associated with cognitive disorders at the end of life involve prevention, identification, intervention, and supportive care issues.

Preventing Terminal Anguish. As terminal anguish is related to unresolved issues, often involving guilt,\textsuperscript{120} it is important to encourage the patient and family to identify and to address unresolved issues. This sensitive topic can be introduced by telling the patient that many times people hold old grudges and hurts inside because they seem too painful or difficult to talk about. However, the common experience is that not talking about these concerns makes treating somatic symptoms even more emotional and difficult.

Preventing Delirium in the Dying. As medications are the most common reversible and preventable cause of delirium,\textsuperscript{129} patients and families require education on the proper dosing
Delirium can be caused by both taking too much medication (leading to toxicity) or too little (causing discomfort or potential withdrawal). It is important for nurses who care for patients in home care and clinic settings to review all medications with the patient and primary caregiver. Ideally, patients or family caregivers will recognize both the generic and trade names of their medications. Patients and family caregivers need to know the schedule for each medication, the side effects of each to report to their clinicians, and what to do if they should lose or run out of a medication. Medication charts, pillboxes, and medication information cards or sheets may be useful tools.

Patients and family also need to understand that any discomfort that is not adequately addressed can lead to complications, such as feeling nervous, confused, or worse. Thus, education for managing symptoms such as pain, nausea, constipation, and insomnia is an important component of the teaching plan to prevent delirium.19,21

Knowing that sensory deprivation, sensory overload, and unfamiliar or threatening surroundings may contribute to the development of delirium, it becomes evident that patient and family education should include evaluating the patient’s sensory environment and developing strategies to provide appropriate levels of sensory stimulation. For some patients, this may mean encouraging interactions with caregivers and others (e.g., hospice volunteers), having the television or radio at a level pleasing to the patient, being sure the patient can see out a window to sense day and night clues, encouraging touch (e.g., massage or range-of-motion exercises), and assuring that the patient uses any needed sensory aides, such as eyeglasses or hearing aids.

Conversely, the patient who is in an environment where sensory overload is a potential requires education on decreasing sensory stimuli. Acute care settings are well known for the potential for sensory overload. However, many times, the potential for sensory overload in the home is not assessed. The combination of noises from vacuums, mixers, dishwashers, televisions, radios, conversations, and patient equipment (e.g., oxygen concentrators) can be overwhelming. In the susceptible patient, it may be helpful to close room doors, to run dishwashers or other equipment at different times of the day, to turn off or turn down televisions and radios when conversing, or to unplug the telephone at certain times of the day.

Being in a strange or threatening environment can contribute to delirium. Should a patient need to be admitted to an acute care or extended care setting, it is important to make that environment as familiar as possible. Encourage the patient and family to bring in familiar photographs or objects, establish a plan for familiar persons to visit regularly, teach family to greet their loved one at eye level, and encourage the use of touch, since this is very reassuring to the patient.

**Early Identification of the Symptoms of Delirium.** The prodromal symptoms of delirium may be easily overlooked. It is not uncommon for persons with advanced diseases to feel restless, anxious, depressed, irritable, angry, or emotionally labile. These symptoms may go unnoticed, only to be recalled later in family interviews.10 Therefore, it is important to teach the patient and family to report any new feelings of uneasiness, anxiety, restlessness, or mood changes.

**Lessening the Severity of the Symptoms of Delirium.** The individual experiencing delirium may be very frightened regarding what is happening. Clinicians need to provide reassurance that delirium is usually temporary and that the symptoms are part of a medical condition.109 This intervention may significantly decrease fear and anxiety. The purpose of all supportive measures needs to be explained to both the patient and the family. For example, discuss the purpose of any hydration ordered, the importance of adequate rest, and the rationale for orienting interactions on the part of nursing staff and family.130

The family should be informed regarding the fluctuating nature of delirium19,21 to prepare them for the changes in behavior and to prevent them from misinterpreting these frequent changes. Reorienting the patient to time, place, and persons in the environment may assist him or her to stay oriented. Repetition is important to compensate for memory impairment.120 Thus, the family should be taught to correct the patient’s orientation errors gently and regularly. If, however, correcting orientation errors leads to increased distress in the patient, this strategy should be discontinued.19,21

The delirious patient is at risk for misinterpreting the environment. The family should be encouraged to evaluate the patient’s environment for over- or undersensory stimulation. Interventions to correct the potential for sensory deprivation or overload, as mentioned above, may be appropriate.

Behaviors associated with delirium can be distressing for family caregivers to observe and may lead to fears that their loved one has “gone crazy.”109,120 The family needs to hear that delirium is the result of a biological disorder and that the symptoms are generally temporary. The family should also be included in discussions of current, predicted, or resolving delirium in the patient. In addition, the family should be encouraged not to take behavior personally.22

**Teaching Following an Episode of Delirium.** Follow-up teaching will include a discussion with the patient about the apparent cause of delirium so that both the patient and family are aware of risk factors. The individual may or may not recall events during delirious episodes. Some individuals have frightening recollections of the delirious episode. Thus, it is important to assess the presence of any distressing memories. Extra psychotherapeutic support to work through the experience may be appropriate.2,109

**Case Study**

**M.H., a Patient with Metastatic Breast Cancer**

M.H. is a 54-year-old Caucasian woman who has self treated her metastatic breast cancer in the belief that herbs and vitamins would help her disease better than what the
traditional medical community could provide her. She had been living with her illness for more than 5 years and had allowed her right breast to ulcerate on several occasions, leaving a huge scar and disfigured chest wall, with no resemblance of breast tissue. M.H. was the owner of a natural herbs-and-vitamins business with her husband, who had died 5 months before from a metastatic malignancy of unknown etiology. M.H. had two young adult daughters who both lived out of town.

M.H. was enrolled in a local hospice program and was receiving opioids for treatment of severe pain. Her primary caregiver (her best friend, and a registered nurse) contacted a local palliative care nurse practitioner (NP) to evaluate her status, believing that she was receiving too many opioids, which were contributing to significant side effects such as sedation, cognitive clouding, constipation, nausea, vomiting, and anorexia. The NP made a home visit to evaluate M.H. and quickly identified her reluctance to use and embrace the practices offered by Western medicine. Therefore, after a long discussion with the patient and her caregiver, the NP was allowed to perform a limited physical examination. M.H. would not allow the NP to evaluate her affected breast or palpate for associated lymphadenopathy; the NP was allowed to obtain vital signs and listen to both heart and lung sounds. Because of her distrust of the medical community, M.H. had limited diagnostics performed to a bone scan, which she received from an alternative therapy clinic, and which revealed extensive bone metastasis. The NP focused her attention on the medications that the patient had been prescribed and noted 100 mcg of transdermal fentanyl, 80 mg of sustained-release morphine every 8 hours, and 30 mg of immediate-release morphine for incident pain. She was prescribed lorazepam 1 mg every 4 to 6 hours for nausea and vomiting and was using her own preparation of cascara for constipation as needed. M.H. also had promethazine 50-mg suppositories in her refrigerator and was using them every 6 hours for her nausea and vomiting.

The NP noted that M.H. required direct control of her medical management and, despite the inappropriate use of medications, noted that it would require deliberate time and energy to gain trust and confidence in the NP to better control her symptoms. It was also clear to the NP that M.H. was extremely nervous and agitated about her illness, and during the home visit, she learned that M.H. was planning to travel to a clinic in Mexico, where she believed she would be cured of her disease. The NP focused on the immediate needs and identified the following problems that could promptly be managed: dehydration, constipation, unmanaged pain, anorexia, anxiety, agitation, sedation, and cognitive clouding, and, despite the patient’s insistence that she was not depressed. The NP initiated hydration of 1000 mL of NAACL 0.9% IV over 2 hours, discontinued lorazepam and fentanyl, changed her sustained-release opioid schedule to a 12-hour schedule (not changing the total daily dose), and discouraged the use of promethazine. The NP, in conversation with her collaborative physician, then prescribed dexamethasone 16 mg every day (to support her complaints of somatic pain, assist with nausea and vomiting, and help with anorexia and depression), haloperidol 2 to 5 mg every 4 to 6 hours for complaints of nausea and vomiting and agitation, and encouraged routine use of her cascara (every 8 hours) to aid her constipation. The NP planned a return home visit the next day to evaluate her symptoms. During the next visit, the patient and caregiver were both ecstatic about the benefit and changes in her condition, and by the following Sunday the patient attended religious services, which she had been unable to attend for many weeks.

M.H. continued to do extremely well and began to plan her trip to Mexico seeking cure. Because of her physical improvement, she did travel to Mexico and returned home only to become very ill from the treatment she had received. The NP was consulted and upon arrival to her home realized that M.H. was actively dying and that she was extremely agitated, since she was convinced that it would have been the “miracle.” Her two daughters had been called from out of town and were present during the home visit, along with the caregiver and hospice nurse. M.H. was having episodes of insomnia, calling out inappropriately at night, and refusing to stay in bed. Because M.H. had done so well before her travel, many of the medications that she had been taking previously were discontinued. While in the Mexican clinic, she had discontinued all medications except her opioids. The NP noted the apparent changes in the patient’s cognition and considered hypercalcemia and dehydration, but M.H. refused laboratory analysis. She did, however, accept hydration through hypodermoclysis. The NP also prescribed haloperidol 5 mg every 6 hours, discussing its benefits with the family, caregiver, and hospice nurse.

The NP was frantically contacted the next day because M.H., despite her weakness, was extremely agitated and on her hands and knees in her hospital bed, rocking back and forth and yelling out at her family. The NP made an emergency home visit and inquired about the use and amount of haloperidol. She promptly discovered that the hospice nurse did not feel comfortable using haloperidol and had discouraged the family from its use, instead encouraging the use of lorazepam 2 mg every 4 hours. The NP was faced with a challenging patient and family situation—they apparently had gone online to learn more about haloperidol because the hospice nurse was not in favor of this intervention, and were reluctant to use it. After a prolonged discussion of the benefits associated with this intervention, haloperidol was initiated subcutaneously at 10 mg until the patient became less agitated (lorazepam was titrated to a low dose 0.5 mg sublingual every 12 hours). M.H. was then able to relax and be placed back in her bed. She kept her eyes closed yet was able to respond appropriately to questions regarding her comfort. The NP suggested that the caregiver continue with haloperidol 5 mg subcutaneous injections every 6 hours. This intervention was successful and M.H. died early the next morning, peaceful and surrounded by her family.
Summary

This case illustrates many issues related to a dying patient who experiences agitation and confusion. M.H. required individualized assessment and respect for her beliefs regarding her disease and treatment. The NP’s skilled assessment of her multiple and changing symptoms was also essential. This case also illustrates the necessity of distinguishing related symptoms and modifying drug regimens as symptoms progress, particularly at the end of life, and including the participation of the family in the plan of care, especially when the patient is dying at home.

Conclusion

The nurse is the bedside advocate in discerning changes in the patient’s cognition. Early and prompt recognition of cognitive changes can help to initiate appropriate interventions and discourage the progressive nature of delirium. Delirium is a broad category for many alterations in the cognitive realm and can be reversible. Becoming better acquainted with the assessment, etiology, and interventions to promote an improved quality of life is essential when providing optimal symptom management to ease the transition for the dying patient.

Sexuality

My husband and I have been married for over 50 years. When I was diagnosed with ovarian cancer 9 months ago, it was devastating for both of us. The nights I spent in the hospital after my exploratory surgery were some of the roughest times in my life. Before then, I could count on one hand how many nights since our marriage we had not spent together in the same bed. Now it seems that number is growing exponentially. I wish we could have some time alone together. Now that the doctors have said the chemotherapy isn’t working, there seems to be a steady stream of people through our house, both night and day. Our three grown children live in the area and often drop by to see us. Along with them come their spouses and grandchildren. Hospice has started paying daily visits, and friends and neighbors come by often. I long for just a little privacy with my husband. Just to hold each other, maybe snuggle and kiss or even just fall asleep in each other’s arms would mean the world to me.—A patient with end-stage ovarian cancer

Sexuality is a basic aspect of human life, seen by many as fundamental to “being human.” It is a complex phenomenon that basically comprises the greatest intimacy between two humans. The ability to give and to receive physical love is very important for many individuals, even through the trajectory of an incurable illness.1,2 The ability to maintain close sexual relations can be viewed as maintaining an essential part of one’s “self.” Sexuality can affirm love, relieve stress and anxiety, and distract one from the emotional and physical sequelae of an eventually terminal chronic illness. Sexual expression can foster hope and accentuate spirituality. Health care providers in all clinical settings where palliative care is provided can be pivotal in facilitating the expression of sexuality in the terminal stages of life. Holistic palliative care throughout the trajectory of an incurable illness should include the promotion of sexual expression and assistance in preventing or minimizing the negative effects of an illness’s progression on a couple’s intimacy. Sexual partners’ caring can comfortably include sexual expression if both parties are interested and able.

Importance of Physical Intimacy

The patient and family are at the center of palliative care. A patient’s desire for and interest in maintaining sexual relations is highly variable. Some may find expression of physical love an important aspect of their life right up to death, while others may relinquish their “sexual being” early in their end-of-life trajectory. Each individual’s identity is influenced, in part, by his or her sexual identity. Roles between spouses or sexual partners are additionally defined by the sexual intimacy between them.

Sexual integrity can be both altered and compromised during the course of an incurable disease, deleteriously affecting both the identity and the role fulfillment of the affected persons. Health care providers should not make assumptions...
about the level of interest or capacity a couple has for physical intimacy.

Sexuality goes far beyond “sexual intercourse.” Sexuality may encompass physical touch of any kind, as well as experiences of warmth, tenderness, and the expression of love. The importance of physical intimacy vacillates throughout a relationship and may be diminished or rekindled by a superimposed illness. Long-term palliative care providers may see sexual desire and expression ebb and flow between a couple throughout the course of care. The patient may view sexual expression as an affirmation of life, a part of being human, a means to maintain role relationships, or the expression of passion in and for life itself. Some patients may view sexual expression as an essential aspect of their being, while others may see it as ancillary or unimportant. Some patients may enter palliative care with an established sexual partner; some may lose a partner during this period through separation, divorce, or widowhood; and others may begin a relationship during this time. Some patients may have several sexual partners; some couples may be gay or lesbian; while others, without a sexual partner, may gain pleasure by erotic thoughts and masturbation. All of these scenarios are within the realm of the palliative care provider’s patient base. Understanding the various forms of sexual expression and pleasure is paramount in providing comprehensive care.

A sexual partner’s interest and ability to maintain sexual relations throughout the palliative care trajectory can also be affected by many variables. Sexual expression may be impeded by the partner’s mood state (anxiety, depression, grief, or guilt), exhaustion from caregiving and assuming multiple family roles, and misconceptions about sexual appropriateness during palliative care. Anxiety and depression have profound effects on sexual functioning. Decreases in libido and sexual activity result from depressive and anxious states. A partner may feel that the patient is “too ill” to engage in sexual activity. In turn, the partner may feel remorse or guilt for even thinking about their loved one in a sexual capacity during this time. Partners may fear that they may injure their loved one during sexual activity due to their perceived or actual weakened state or appearance. Furthermore, a partner may have difficulty adjusting to the altered physical appearance of the patient (cachexia, alopecia, stomatitis, pallor, amputation, etc.). The role of caregiver may seem incompatible with that of sexual partner. As the ill partner’s health deteriorates, the well partner may assume caretaking roles that may seem incompatible with those of a lover. Furthermore, the myriad of responsibilities sequentially assumed by the well partner may leave him or her exhausted. This can impede sexual interest and performance. Finally, the partner may harbor misconceptions about sexual relations with a terminally ill partner, including diminishing the patient’s waning energy reserves or causing the illness to progress more rapidly.

Cultural issues may also play a part in the couple’s willingness or interest in maintaining sexual intimacy during palliative care. In Part IX of this book, the international perspective of palliative care is addressed. There exists tremendous diversity among cultural, religious, and spiritual beliefs in relation to sexual intimacy and death. Culture often guides interactions between people, even the mores within sexual interactions. Culturally competent health care providers should take into consideration the effect of culture on sexual expression between a couple during palliative care. For example, does the couple possess the same cultural identity? If not, are their identities similar in respect to beliefs about intimacy? What are the couple’s health, illness, and sexual beliefs and practices? What are their customs and beliefs about intimacy, illness, and death? Issues such as personal space, eye contact, touch, and permissible topics to discuss with health care providers and/or members of the opposite sex may influence one’s ability to intercede within the realm of intimate relations. A cultural assessment is key to determining if these factors are an issue. Variations in sexual orientation must also be considered within the area of cultural competence. The beliefs, actions, and normative actions of homosexual and bisexual couples are important considerations when providing palliative care to a couple with alternate sexual expression. Gay and lesbian couples may be offended by the assumption that they are heterosexual. An example demonstrating the need for acknowledging and respecting individual sexuality follows:

**CASE STUDY**

**A 67-Year-Old Man with Prostate Cancer**

A 67-year-old man dying of prostate cancer once stated, “I am gay but I was married years ago and have three grown children. I have maintained a close supportive relationship with my ex-wife and children. However, for the past 17 years I’ve been in a homosexual relationship with Todd. We are very close emotionally, spiritually, and physically. We have been very forthright about our sexual orientation with our family and friends, but it is difficult when I’m admitted to the hospital. Both my ex-wife and my partner visit me regularly. The staff acknowledge my ex-wife but seem to think Todd is my business partner because I first introduced him as ‘my partner.’ From the onset, this was an embarrassing assumption on their part, and one I felt awkward in correcting. I have Todd accompany me more often than my ex-wife, but they see him as a friend who gives me rides. I know I should just come right out and explain the nature of my relationship; the problem is, I see so many different providers. I feel like I would have to keep going over this again and again. I don’t want to be put in this position repeatedly. Todd is very frustrated by this misunderstanding, and I hate to see him upset. It is difficult enough to be going through the terminal cancer experience without adding another layer of embarrassment and confusion.”

Developmental issues also play a part in the patient’s ability to maintain intimacy during palliative care. Often, health care providers assume sexual abstinence in the elderly and, to some
degree, in adolescents and unmarried young adults. However, intimacy may be a vital part of these individuals’ lives. Chronological age may or may not be a determination of sexual activity. For underage patients, parental influence may interfere with the ability to express physical love. Likewise, the elderly may be inhibited by perceived societal values and judgments about their sexuality. Maintaining an open, nonjudgmental approach to patients of all ages, sexual orientations, and marital status when inquiring about intimacy aspects will foster trust and communication.

**Privacy**

One of the main external obstacles to maintaining intimate relations during palliative care is the lack of privacy. In Part VI of this book, the various settings in which end-of-life care may take place and the concomitant issues raised within each setting are addressed. In the acute care setting, privacy is often difficult to achieve. However, this obstacle can be removed or minimized by recognizing the need for intimacy and making arrangements to ensure quiet, uninterrupted time for couples. Private rooms are, of course, ideal. However, if this is not possible, arranging for roommates and visitors to leave for periods of time is necessary. Furthermore, a sign should be posted on the door that alerts health care providers, staff, and visitors that privacy is required. Finally, many rooms in the acute care setting have windows as opposed to walls, requiring the use of blinds and/or curtains to assure privacy. The nurse should offer such strategies rather than expecting patients to suggest privacy measures.

Similar issues may arise in the long-term care environment. If privacy is a scarce commodity, assisting couples to maintain intimate relations as desired is crucial in providing holistic care. Nurses in long-term care can initiate strategies similar to those enumerated for the acute care setting. Furthermore, this issue may be even more paramount to the patient because often the stay in long-term care is quite extended. In both the acute care and long-term care settings, nurses can play a vital role in setting policy to allow for the expression of intimacy.

Home care may present an array of different obstacles for maintaining intimate relations. The ongoing presence of a health care provider other than the sexual partner is such an obstacle. Furthermore, the home setting is often interrupted by professional visits as well as visits from family, friends, and clergy. These visits may be unplanned or unannounced. The telephone itself may be an unwelcome interruption. Furthermore, the patient may have been moved from a more private, bedroom setting to a more convenient central location, such as a den or family room, to aid care giving and to maintain an integral role in family life. However, this move does not foster the privacy usually sought for intimate activity. There may not be a door to close. Alternately, proximity of the patient’s bed to the main rooms of the house may inhibit a couple’s intimate activities. Negotiating for private time is often necessary.

Necessary steps to maintaining sexual relations include scheduling “rest periods” when one will not be disturbed; turning the ringer on the phone off; asking health care providers, friends, and clergy to call before visiting; and having family members allow periods of uninterrupted time.

**CASE STUDY**

**A 26-Year-Old Woman with Hodgkin’s Disease**

“I am a single woman but have been in a serious relationship for the past 2 years. My boyfriend has been very understanding and supportive during my diagnosis and treatment for Hodgkin’s disease. Sex is a very important part of our relationship. We have lived together for the past year. I was admitted to the hospital several days ago. The nurses, doctors, and others come and go all day long. I wanted a private room but really couldn’t afford the extra expense. One night, just before visiting hours were over, we decided to try to have a ‘quickie.’ We thought my roommate was asleep and tried to be very quiet. We pulled the curtains around the bed and turned off the lights. All of a sudden, the light went on and the curtain was pulled back. Come to find out my roommate heard the noise I was making and thought I was having difficulty breathing. She had put on her call light for the nurse. We were so embarrassed. My boyfriend left quickly and I’m afraid I won’t see him again. I think this is just too much for a 28-year-old guy.”

**Sexual Assessment**

The promotion or restoration of sexual health begins with a sexual assessment. The assessment should include the patient as well as his or her partner. Securing permission to include the sexual partner is necessary. For the nurse to perform this assessment, she or he must be comfortable with the topic of sexuality. Comfort with one’s sexuality conveys comfort to others. Additionally, the nurse’s values, beliefs, and attitudes regarding sexuality greatly influence the capacity to discuss these issues in a nonjudgmental way. Perceived insufficient knowledge on the part of the health care provider is often an obstacle to frank sexual discussions. Additional sexual education and consistent assessment and counseling approaches will allay this discomfort. Education can be gained informally via discussions with colleagues and through consultation with experts in the area of human sexuality. Formal training is gained through in-service education offerings, workshops, and sexual-attitude reassessment programs. Knowledge can also be fostered by keeping abreast of new developments within the field by attending conferences and reviewing journals and professional information via the Internet.

Assessment of sexuality begins with a sexual history and is then supplemented by data regarding the patient and partner’s
physical health as it influences intimacy, psychological sequelae of the chronic illness, sociocultural influences, and possible environmental issues. Since sexual health is viewed as a relative matter, it is essential to determine if the couple is satisfied with their current level of sexual functioning. Celibacy, for example, may have been present in the relationship for years. However, the trajectory of palliative care may have forced celibacy on an otherwise sexually active couple. Determining the couple’s need for interventions and assistance in this area is key. The health care provider has many interventions available to prevent or minimize the untoward effects that palliative care may impose on intimacy.

Obtaining a sexual history and performing a subsequent sexual assessment can be augmented using several communication techniques—assuring privacy and confidentiality; allowing for ample, uninterrupted time; and maintaining a nonjudgmental attitude. Addressing the topic of sexuality early in the relationship with a palliative care patient legitimizes the issue of intimacy. It delivers the message that this is an appropriate topic for concern within the professional relationship, and is often met with relief on the part of the patient and couple. Often, sexuality concerns are present but unvoiced.

Incorporating several techniques of therapeutic communication enhances the interview. These techniques include asking open-ended questions (“Some people who have an incurable illness are frustrated by their lack of private time with their spouse/sexual partner. How is this experience for you?”); using questions that refer to frequency as opposed to occurrence (“How often do you have intimate relations with your wife/husband/partner?” as opposed to “Do you have intimate relations with your wife/husband/partner?”); and “unloading” the question (“Some couples enjoy oral sex on a regular basis, while others seldom or never have oral sex. How often do you engage in oral sex?”). This last technique legitimizes the activity and allows the patient to feel safe in responding to the question in a variety of ways.

Gender and age may also play a part in the patient’s comfort with sexual discussions. An adolescent boy may feel more comfortable discussing sexual concerns with a male health care provider, whereas an elderly woman may prefer to discuss sexual issues with a woman closer to her own age. Assessment of these factors may include statements like the following: “Many young men have questions about sexuality and the effect their illness may have on sexual functioning. This is something we can discuss or, if you’d be more comfortable, I could have one of the male nurses talk to you about this. Which would you prefer?”

If the sexual history reveals a specific sexual problem, a more in-depth assessment is warranted. This would include the onset and course of the problem, the patient’s or couple’s thoughts about what caused the problem, any solutions that have been attempted, and potential solutions and their acceptability to the patient/couple. For example, use of a vibrator in the case of male impotence may be entirely acceptable to some couples but abhorrent to others. Determining what is and is not acceptable regarding potential solutions is part of the logical next step in sexual assessment.

Finally, documentation in the patient’s chart should reflect the findings of the sexual assessment. Many institutions have a section for sexual assessment embedded within their intake form. This can be completed and more thorough notes added to the narrative section on the chart. Findings, suggestions for remediation, and desired outcomes should be documented. This will prevent duplication of efforts, communication within the health care team, and continuity of care within the realm of sexual health.

**Interventions to Augment Sexual Health in End-of-Life Care**

The specific sexual needs and concerns of the patient and couple determine the approach and type of intervention. The intervention can address current needs or focus on potential future needs in the form of anticipatory guidance. Although dated, the P-LI-SS-IT model developed by Annon remains a cornerstone in sexual rehabilitation. The assessment phase, previously outlined, comprises the “P,” or permission, phase of this intervention model. Permission simply refers to the openness about discussing sexual concerns. In assessing sexual health, the health care provider has begun intervening in the realm of sexuality. By initiating a discussion about the effects that palliative care may have on an individual’s or couple’s intimate relations, one legitimizes these concerns.

Limited information regarding actual or potential problems is addressed once the assessment phase of the intervention is complete. This is the “LI” of the acronym. Specific information and suggestions can then be given to assist the patient or couple with adapting to changes in intimacy brought on by incurable illness or end-of-life care. Questions can be answered, what is normal can be acknowledged, and myths and misconceptions can be dispelled. False assumptions about intimacy during palliative care can be addressed, and anticipatory guidance regarding what to expect as a result of advancing disease and palliative treatment is included in this discussion.

Specific suggestions (SS) go beyond limited information, and counseling is employed to rectify specific problems or to attain a mutually stated goal. A stated goal is key to this phase because the resultant plan will aim at attaining that outcome. Specific suggestions usually pertain to communication, symptom management, and alternate physical expression. Fostering open communication between the couple about sexuality in end-of-life care is essential. Candid discussions regarding their emotional response to this phase of their relationship, their fears and concerns, and their hopes and desires are included in these interactions. Symptom management is essential to optimizing sexual expression. The following section of this chapter addresses specific symptoms, their effect on the expression of intimacy, and strategies to effectively manage them while not compounding sexual problems. Alternate expressions of
physical intimacy may be necessary if sexual disruption is due to organic changes. If intercourse is difficult, painful, or impossible, the couple may have to expand their sexual repertoire. A thorough discussion of the couple's values, attitudes, and preferences should be done before suggesting alternatives. Using language that is understandable to the patient/partner is essential. However, the use of slang or street language may be unacceptable to the health care provider. Therefore, defining terms early in the discussion will alleviate this potential problem.

There are many ways of giving and receiving sexual pleasure—genital intercourse is only one way of expressing physical love. Other suggestions include hugging, massage, fondling, caressing, cuddling, kissing, hand-holding, and masturbation, either mutually or singularly. Sexual gratification may be derived from manual, oral, and digital stimulation. Intramural, anal, and intramammary intercourse are also options if the female partner is unable to continue vaginal penetration.

Intensive therapy (IT), the last stage of this model, is not usually suggested in end-of-life care. This therapy is generally for couples who have long-standing sexual or marital problems. The feasibility of this type of therapy during palliative care for a terminal illness is questionable. 

Management of Alterations in Sexual Functioning During End-of-Life Care

Terminal illness and end-of-life care can interfere with sexual functioning in many ways. All of the following can impact sexual functioning: physiological changes; tissue damage; other organic manifestations of the disease; attempts to palliate the symptoms of advancing disease, such as fatigue, pain, nausea and vomiting; and psychological sequelae such as anxiety, depression, and body-image changes. Environmental issues that may affect sexual expression were addressed in the previous section. Management of the patient's biological and psychological sequelae is addressed below.

Fatigue

Fatigue may be due to an array of factors. In Chapter 7, the etiology and management of fatigue were thoroughly addressed. Fatigue may render a patient unable to perform sexually. If fatigue is identified as a factor in the patient's ability to initiate or maintain sexual arousal, several strategies may be suggested to diminish these untoward effects. Minimizing exertion during intimate relations may be necessary. Providing time for rest before and after sexual relations is often a sufficient strategy to overcome the detrimental effects of fatigue. Likewise, avoiding the stress of a heavy meal, alcohol consumption, or extremes in temperature may be helpful. Experimenting with positions that require minimal patient exertion (male-patient, female astride; female-patient, male astride) is often helpful. Finally, timing should be taken into consideration. Sexual activity in the morning upon awakening may be preferable over relations at the end of a long day. Planning for intimate time rather than spontaneity can be a beneficial strategy.

Pain

Sexual arousal and performance are often impaired by the presence of pain. Additionally, the use of pain medication (especially opiates) can interfere with sexual arousal. In Chapters 5 and 6, the issues of pain assessment and management are discussed in a comprehensive manner. The goal of pain therapy is to alleviate or minimize discomfort. However, in attaining that goal, sexual responsiveness (i.e., libido or erectile function) may be hindered. Temporarily adjusting pain medications or experimenting with complementary methods of pain management should be explored. For example, using relaxation techniques before intimacy may be helpful. Romantic music may decrease discomfort through distraction and relaxation, while enhancing sexual interest. Sexual activity itself can be viewed as a form of distraction and subsequent relaxation. The couple should be encouraged to explore positions that offer the most comfort. Traditional positions may be abandoned for more comfortable ones, such as sitting in a chair or a side-lying position. Pillows can be used to support painful limbs or to maintain certain positions. A warm bath or shower before sexual activity may help pain relief and be seen as preparatory to intimate relations. Massage can be used as both an arousal technique and a therapeutic strategy for minimizing discomfort. Finally, suggesting the exploration of alternate ways of expressing tenderness and sexual gratification may be necessary if the couple's traditional intimacy repertoire is not feasible due to discomfort.

Nausea and Vomiting

Nausea and vomiting are common during the palliative care trajectory and negatively impact sexual functioning. Chapter 9 discusses the etiology and treatment of these symptoms. There are many medications that suppress nausea; however, they may interfere with sexual functioning due to their sedative effects. If the patient complains of sexual difficulties secondary to treatment for nausea and vomiting, an assessment of the prescribed antiemetics may shed light on a pharmacological culprit. Using alternate nonpharmacological methods to control nausea and vomiting or changing to another antiemetic may be warranted. Such strategies include eating small and frequent meals, serving foods at room temperature, avoiding spicy foods, assuring a well-ventilated dining area, and using relaxation and distraction techniques. Providing fresh air through an open window in the bedroom, for example, may decrease noxious olfactory stimuli. As with fatigue, timing may be an important consideration for intimate relations. If the patient/couple notes that nausea is more prevalent during a certain time of the day, planning for intimacy at alternate times may circumvent this problem.
Neutropenia and Thrombocytopenia

Neutropenia and thrombocytopenia, per se, do not necessarily interfere with intimacy, but they do pose some potential problems. Sexual intimacy during neutropenic phases may jeopardize the compromised patient. Severe neutropenia predisposes a patient to infection. Close physical contact may be inadvisable if the sexual partner has a communicable disease, such as an upper respiratory infection or influenza. Specific sexual practices, such as anal intercourse, are prohibited during neutropenic states due to the likelihood of subsequent infection. The absolute neutrophil count, if available, is a good indicator of neutropenic status and associated risk for infection. Patient and partner education about the risks associated with neutropenia is essential.

Thrombocytopenia and the associated risk of bleeding, bruising, or hemorrhage should be considered when counseling a couple about intimacy issues. Again, anal intercourse is contraindicated due to risk for bleeding. Likewise, vigorous genital intercourse may cause vaginal bleeding. Indeed, even forceful or energetic hugging, massage, or kissing may cause bruising or bleeding. Preventative suggestions might include such strategies as gentle lovemaking, with minimal pressure on the thrombocytopenic patient, or having the patient assume the dominant position to control force and pressure.

Dyspnea

Dyspnea is an extremely distressing occurrence in the end-of-life trajectory. In Chapter 13, the management of this symptom is reviewed. Dyspnea, or even the fear of initiating dyspnea, can impair sexual functioning. General strategies can be employed to minimize dyspnea during sexual play. These can include using a waterbed to accentuate physical movements, raising the dyspneic patient’s head and shoulders to facilitate oxygenation, using supplementary oxygen and/or inhalers before and during sexual activity, performing pulmonary hygiene measures before intimacy, encouraging slower movements to conserve energy, and modifying sexual activity to allow for enjoyment and respiratory comfort.

Neuropathies

Neuropathies can be a result of disease progression or complication of prior aggressive treatment. Neuromuscular disturbances are discussed in depth in Chapter 18. Neuropathies can manifest as pain, paresthesia, and/or weakness. Depending on the location and severity of the neuropathy, sexual functioning can be altered or completely suppressed. Management or diminution of the neuropathy may or may not be feasible. If not, creative ways to evade the negative sequelae of this occurrence are necessary. Such strategies might include creative positioning, use of pillows to support affected body parts, or alternate ways of expressing physical love. The distraction of intimacy may temporarily minimize the perception of the neuropathy.

Mobility and Range of Motion

Mobility issues and compromised range of motion may interfere with sexual expression. Similar to issues related to fatigue, a decrease in mobility can inhibit a couple’s customary means of expressing physical love. A compromise in range of motion can result in a similar dilemma. For example, a female patient may no longer be able to position herself in such a way as to allow penile penetration from above due to hip or back restrictions. Likewise, a male patient may have knee or back restrictions that make it impossible for him to be astride his partner. Regardless of the exact nature of the range-of-motion/mobility concern, several suggestions can be offered. Experimenting with alternate positions, employing relaxation techniques before sexual play, massage, warm baths, and exploring acceptable alternative methods of expressing physical intimacy should be encouraged.

Erectile Dysfunction

Erectile dysfunction can be caused by physiological, psychological, and emotional factors. These factors include vascular, endocrine, and neurological causes; chronic diseases, such as renal failure and diabetes; and iatrogenic factors, such as surgery and medications. Surgical severing of the small nerve branches essential for erection is often the untoward effect of radical pelvic surgery, radical prostatectomy, and aortoiliac surgery. Vascular and neurological causes may not be reversible; however, endocrine causes may be minimized. For example, the use of estrogen in advanced prostate cancer may be terminated in palliative care, thus allowing for the return of erectile function. Many medications decrease desire and erectile capacity in men. The most common offenders are antihypertensives, antidepressants, antihistamines, antispasmodics, sedatives or tranquilizers, barbiturates, sex hormone preparations, narcotics, and psychoactive drugs. Often, these medications cannot be discontinued to permit the return of erectile function. For those patients, penile implants may be possible. The use of sildenafil (Viagra), vardenafil HCl (Levitra), tadalfil (Cialis), and yohimbine (Yohimbine) have not been researched in the area of terminal care. These medications are classified as selective enzyme inhibitors. They relax smooth muscle, increase blood flow, and facilitate erection. If a vascular component is part of the underlying erectile dysfunction, the use of one of these medications may correct the problem. Certainly, contraindications such as underlying heart disease and other current medications should be taken into consideration. Otherwise, digital or oral stimulation of the female partner may be suggested as well as use of a vibrator, if that is acceptable.

Dyspareunia

Dyspareunia, like erectile dysfunction, can be caused by physiological, psychological, and emotional factors. These factors include vascular, endocrine, and neurological causes as well as
iatrogenic factors such as surgery and medications.\textsuperscript{13,12,14,15} Again, while vascular and neurological causes may not be reversible, endocrine causes may be minimized. For example, the use of estrogen replacement therapy (ERT), vaginal estrogen creams, or water-soluble lubricants may be helpful in diminishing vaginal dryness, which can cause painful intercourse. Gynecological surgery and pelvic irradiation may result in physiological changes that prevent comfortable intercourse. Postirradiation changes, such as vaginal shortening, thickening, and narrowing, may result in severe dyspareunia. For women, as with male patients, many medications decrease desire and function. These drugs include antihypertensives, antidepressants, antihistamines, antispasmodics, sedatives or tranquiliizers, barbiturates, sex hormone preparations, narcotics, and psychoactive drugs.\textsuperscript{10–13} Often, these medications cannot be discontinued to permit the return of sexual function. For those patients, digital or oral stimulation of the male partner may be suggested, if acceptable. Additionally, intrathigh penetration may be suggested to women who find vaginal intercourse too painful.

**Body Image Disturbances**

Sexuality is closely related to how one views oneself in the physical sense. An incurable illness and concomitant end-of-life care can alter one’s physical appearance. Additionally, past treatments for disease often irreversibly alter body appearance and function. Issues such as alopecia, weight loss, cachexia, the presence of a stoma, or amputation of a body part, to name a few, can result in feelings of sexual inadequacy and/or disinterest. End-of-life care can focus on the identification and remediation of issues related to body image changes. Although an altered appearance may be permanent, counseling and behavior modification, as well as specific suggestions to minimize or mask these appearances, can improve body image to a level compatible with feelings of sexual adequacy and empowerment.

The use of a wig, scarf, or headbands can mask alopecia. Some patients, rather than try to conceal hair loss, choose to emphasize it by shaving their heads. Weight loss and cachexia can be masked through clothing and the creative use of padding. The presence of an ostomy can significantly alter body image and negatively affect sexual functioning. Specific interventions for minimizing the effect that the presence of an ostomy has on sexual functioning depend, in part, on the particular type of ostomy. Some patients are continent, while others need an appliance attached at all times. If the patient has a continent ostomy, timing sexual activity can allow for removal of the appliance and covering the stoma. If the ostomy appliance cannot be safely removed, the patient should be taught to empty the appliance before intimate relations and to use a cover or body stocking to conceal the appliance. Alternate positions may also be considered, and in the event of a leak, sexual activity can continue in the shower. The United Ostomy Association (http://www.uoa.org) publishes four patient information booklets on sexuality and the ostomate: Sex, Courtship, and the Single Ostomate by D.P. Binder, Sex and the Female Ostomate by G.L. Dickman and C.A. Livingston, Sex and the Male Ostomate by E. Gambrell, and Gay and Lesbian Ostomates and Their Caregiver by the Gay Lesbian Organization.

**Anxiety and Depression**

Anxiety and depression related to the incurable and terminal aspects of the disease may interfere with sexual desire and response. As two of the most common affective disorders during end-of-life care, they are thoroughly discussed in Chapter 19. Both anxiety and depression have profound effects on sexual functioning.\textsuperscript{9} Decreases in sexual desire, libido, and activity are common sequelae of these affective disorders. However, some interventions, especially pharmacological management, can further compromise sexual functioning. A thorough assessment of the patient’s psychological state and an evaluation of the medications currently prescribed for this condition may reveal the source of the problem. Anxiolytics such as lorazepam and alprazolam are commonly prescribed. Antidepressants, such as tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), and monoamine oxidase inhibitors, are often prescribed. All of these have the potential for interfering with sexual functioning.\textsuperscript{10} Unfortunately, one may end up having to choose psychological comfort and compromised intimacy. Alternately, the health care provider may suggest a nonpharmacological approach to the management of these affective disorders, especially if the disorder is mild. Relaxation techniques, imagery, and biofeedback may lower anxiety to a tolerable level. Additionally, the release of sexual tension may itself resolve anxiety. If desire is maintained and function alone is compromised for male patients, the couple may explore alternate ways of pleasing each other. For female patients, use of water-soluble lubricants can offset the interference with arousal if interest remains intact. Once again, open communication between both the couple and the health care provider allows for frank discussions and the presentation of possible alternatives to expressing physical affection during palliative care.

**Summary**

Incurable illness and end-of-life care may result in compromising a couple’s intimacy. To prevent or minimize this, health care providers should assume a leading role in the assessment and remediation of potential or identified alterations in sexual functioning. Clearly, not all couples will find intimacy a concern at this point of their life together. However, if intimacy is desired, all attempts should be made to facilitate this important aspect of life. Many find being physically close to the one they love life-affirming and comforting. As patients draw close to the end of life, they remain human and holistic. Their needs, hopes, and concerns remain as intact as all others. If
those needs and hopes include maintaining intimacy with a partner, this should be included in the assessment and provision of care. The health care provider’s offer of information and support can make a significant difference in a couple’s ability to adjust to the changes in intimacy related to end-of-life care.

The realm of sexual functioning and intimacy during end-of-life care remains an area in which further research is warranted. Much of the information presented in this chapter resulted from clinical practice and inferences made from other, tangentially related research. Incorporating intimacy research into end-of-life care research is a natural and much-needed marriage.

Clinical Interventions, Economic Outcomes, and Palliative Care

“Would you tell me please which way I have to go from here?”
“That depends a good deal on where you want to get to.”
—Lewis Carroll, Alice’s Adventures in Wonderland.

• Key Points
• The scope of nursing and nursing education has expanded to include multiple domains, many of which overlap other disciplines such as wellness, disease prevention, and health services administration.
• Economic outcome is an area in which nursing plays an essential role in providing efficient, cost-effective, and appropriate palliative care.
• Health services research regarding economic outcomes, while limited, may help create a framework for addressing how to make palliative care available to everyone in an ethical, economic, and effective manner.

Why Are Economic Outcomes Important?

Health care spending and health care quality are major problems in the United States, with health care spending reaching $1.6 trillion, a number expected to triple in the next 10 years. In 2002, there was an annual increase of 9.3%. Drug costs and rising hospital expenses fueled much of this spending. The financial costs of cancer are great both for the individual and for society as a whole. The economic burden is likely to increase as the population ages, the absolute number of people treated for cancer increases, and newer technologies and expensive treatments are adopted as standards of care. Already in the year 2004, the National Institutes of Health estimated overall annual costs for cancer to be $189.8 billion, with direct medical costs totaling $69.4 million, and indirect costs from lost productivity to be $16.9 billion due to illness and $103.5 billion due to premature death. Lack of health insurance and other barriers to health care prevent many Americans from receiving optimal medical care. According to the 2003 National Health Interview Survey data, nearly 27% of Americans between the ages of 18 and 24 and 20% of Americans between the ages of 25 and 44 reported not having a regular source of health care. Additionally, 17% of Americans under age 65 have no health insurance, and about one third of older individuals only have Medicare coverage. Nearly one third of all Medicare spending is on patients in their last year of life; we are spending a significant amount on high-technology care for the elderly, and those funds cannot be spent on preventive services or chronic disease conditions for the same population. The pressure on health care funds will increase due to heightened demands for care from an educated elderly population, more elderly long-term survivors, new and expensive technologies, new diseases, and demands for cost cutting. All health care interventions, regardless of intention, active therapy, or palliative care, are delivered at a price. Cost effectiveness of interventions must...
be continually assessed; less is not necessarily better, but whatever is spent must maximize the resources available.\(^8\) The question of when, where, and why to use high-tech interventions falls into the middle of this debate and must be carefully explored.

Care is not optimal for all patients, and quality of palliative care must improve. The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT) showed that half of all dying patients had unnecessary pain and suffering in their final days of life while in the hospital.\(^9\) Cleeland and colleagues found that nearly half of all patients suffer unnecessary pain, even when cared for by oncologists.\(^10\)

The whole neglected issue of cancer care quality is now under discussion, with active efforts to improve it.\(^11\) The relationship of volume to quality is striking\(^12\): (1) a significant (5% to 10%) overall survival advantage at a breast cancer specialty center versus community hospitals\(^13,14\); (2) better survival for testicular cancer patients treated at specialist centers\(^15\); (3) better survival and fewer complications for ovarian cancer surgery performed by specialist gynecological oncologists rather than general surgeons or gynecologists\(^16\); and (4) better survival for prostate cancer patients at high-volume centers.\(^17\) Until the science of palliative care becomes better known, one can reasonably speculate that palliative care will improve in high-volume or specialized centers.\(^18\)

Clearly, there is a need for additional research to address these questions of quality care. We have identified some important questions about economic outcomes and palliative care, which are listed in Tables 22–1 and 22–2.

### The Ethics of Adding Economic Outcomes

In the modern arena of health care, nonmedical concerns, such as cost control, oversight and audit, utilization review, and decreasing liability risk, have assumed a significant role. Some authorities have argued that such management tools are not inherently unethical.\(^19\) Cost control is certainly not so, but should be considered secondary to the goal of quality care. The goals of nursing and medicine are grounded in a tradition of promoting health and providing comfort and relief of suffering in a just manner. Cost control through aggressive disease management, or “critical paths,” may actually promote these goals by making more and/or better care available if we avoid the current systems that reward/pay for hi-tech interventions but fail to reimburse effective low-tech treatments.\(^20\) An example of this discrepancy is that insurance will reimburse a patient-controlled analgesia pump but will not reimburse oral analgesics.

Cost control must be differentiated from profit motivation and entrepreneurship, which have not traditionally been considered the goals of medicine. These activities in the context of

health care are unethical in that they may make medical care more expensive and difficult to access, especially for those who are socially disadvantaged. They may also create further conflicts of interest in already precarious fiduciary relationships between clinicians and their patients. A code of ethics that covers all professionals, rather than medicine alone, might be useful.21

Tolerance of suboptimal care is an equally important ethical issue and one that is rarely mentioned in either ethical or management studies. Studies such as SUPPORT have revealed that many aspects of end-of-life care are still suboptimal. The national dialogue about physician-assisted suicide might also indicate that end-of-life care has not been optimized, thus resulting in despair and frustration so significant as to urge dying persons to consider suicide to end their suffering. If palliative care can be improved and/or made less costly without sacrificing quality, it must be done in the service of promoting the values of beneficence, compassion, and respect for autonomy. Palliative care has emerged as a national movement, with the advent of several important initiatives (e.g., Project on Death in America, Oncology Nursing Society efforts, Education for Physicians on End-of-Life Care by the American Medical Association, established programs such as the Center to Improve Care of the Dying at George Washington University), plus the development of palliative care programs all over the world. The Healthcare Finance Administration’s approval of an International Classification of Diseases-9 code for palliative care was hoped by some to indicate its significance in the health care system.25 The economic outcomes are not known and may be difficult to measure, but regardless, the ethical impetus to correct the deficiency is critical.

Another serious ethical question is the ownership of disease-management models. Should management tools that improve care be protected or available to the general public? If a tool that improved care at a markedly lower cost were developed, one could argue that it should be made available for widespread distribution, much like polio vaccine. Another example would be an algorithm that eased dyspnea rapidly in end-stage disease, with minimal economic impact and no requirement for technology.

Some have argued that budgets should not be balanced with penalty to one group, such as the elderly or those on Medicare.22,23 Many health care goods are rationed justly (benefit versus risk) according to age, such as transplants, coronary bypass, and hemodialysis, based on the theory of equality of opportunity according to ability to benefit from such procedures.24 However, palliative care is different in that age does not determine whether a person stands to benefit. In this circumstance, the ethic of distributive justice supports the concept that medical and social needs dictate who stands to benefit most from palliative care.

Daniels25 reported that “it does not seem reasonable to postulate that the medical needs of the elderly terminally ill are any less than those of younger patients, and indeed they may be greater because of multiple additional pathologies associated with aging.” Sidgwick’s26 argument that each moment of life is equally valuable no matter when it occurs is most poignant in the instance of palliative care. This would also apply to extending palliative care to neonates expected to live only a short time after birth.

Patients may view benefit and toxicity in ways very different from their health care providers and from those who are well. According to a recent study, dying patients would undergo almost any treatment toxicity for a 1% chance of short-term survival, while their doctors and nurses would not; and these decisions were not changed after patients experienced the toxicity of treatment.27 A study of palliative radiotherapy for brain tumor patients showed little survival, modest functional benefit, and a substantial decrease in intellectual function; but most patients and families would still want it.28,29 This is a complex appraisal that needs further study.

**What Is the Right Amount to Spend on Health Care?**

How much to spend on health care cannot be determined without knowing the economic and cultural particulars of a country or even a health system. Blanket statements about a percentage of the gross national product (GNP) may be misleading if a comparison country spends a higher percentage on social net programs but less on direct medical care costs. Comments about health care spending as a percent of the GNP may also reflect opinions about alternative uses; for example, “We should stop spending money on defense and spend it on health care.” In the United States, the amount spent on education has declined from 6% to 5% of the GNP, while the amount spent on health care (especially for the elderly) has risen from 6% to about 14%.30 Clearly, in all countries, the entire system of health...
Should There Be Special Economic or Policy Considerations for Palliative Care?

We believe that, in general, there should be no special considerations for palliative care. Most health care policy analysts and economists would argue that all care should be evaluated equally. For example, a therapy that gains 1 week for 52 patients should be valued as much as a therapy of equivalent cost that gains 52 weeks for 1 patient. Recently, some health economists have argued that time given to those who are most at risk should be valued more (e.g., time added in the last 6 months of life should be given triple value). The analogy was made to food and hunger: a sandwich given to a starving person would be of more intrinsic value than one given to a person who already had many sandwiches. Such discussions, while interesting, are outside the scope of this chapter, but many of the ethical concepts applied to these global discussions have relevance to decisions about palliative care.

The World Health Organization (WHO) has listed priorities for health care. In cancer, palliative care has always been included in the same category as curative therapy. In part, this was done because most palliative care is relatively inexpensive.

Current allocation of resources greatly favors curative care with less support for palliative care. As Figures 22–2 and 22–3 illustrate, WHO advocates a more equal distribution of resources in developed countries and an even greater support of palliative care in developing countries, where most of the population will experience advanced disease rather than cure or long-term survival.

One approach to funding treatments has been based on cost-effectiveness ratios. Laupacis and colleagues in Canada proposed explicit funding criteria: (1) treatments that work better and are less expensive should be adopted; (2) treatments with cost-effectiveness ratios of less than C$20,000 per additional life year (LY) gained should be accepted, with the recognition that they cost additional resources; (3) treatments with cost-effectiveness ratios of $20,000 to C$100,000/LY should be examined on a case-by-case basis with caution; (4) and treatments with cost-effectiveness ratios of greater than C$100,000/LY should be rejected. These criteria are valid in a system where all resources are shared equally; it is not clear how they apply to other health care systems, where resources may not be shared. Alternatively, patients might be allowed to purchase additional insurance for expensive treatments or pay for them out of pocket. In the United States, there has been no accepted answer, but most authorities have agreed on an implicitly defined benchmark of $35,000 to $50,000/LY saved. For example, an individual with a pathological fracture of a femur is sent to the operating room for pinning. This surgery will...
aid in relieving pain, improving function, and probably decreasing other potential complications, such as decubitus ulcer and deep venous thrombosis.

**What Are Important Economic Outcomes?**

Economic outcomes are not different from clinical outcomes, and cost must be considered along with clinical benefit. Only one medical group, the American Society of Clinical Oncology (ASCO), has published recommendations on what benefit is justified to recommend a medical intervention, as listed in Table 22–2. Of note, ASCO could not define the lowest amount of benefit that justified an intervention, for example, 2 weeks of quality survival, but recommended that the benefit be weighed against the toxicity and costs. If cost-effectiveness data are not available, then cost consciousness with attention to lowest costs for comparable results would be appropriate; cost alone is not sufficient since more expensive treatments, such as bone marrow transplantation for relapsed leukemia, may give better survival at reasonable cost effectiveness.

The economic data necessary to make decisions about treatment may be collected in much the same way as clinical information, and standard formats for collection and analysis are now available. Some standard definitions are listed in Table 22–3.

It is important to organize data in a way that balances clinical and cost information side by side, as shown in Table 22–4. Cost effectiveness is the amount of money someone must pay to gain additional months or years of life. The usual benchmark is “life years gained” or LYS. The standard cost-effectiveness question is $\Delta C/\Delta E = (C_2 - C_1)/(E_2 - E_1)$ where $C =$ costs and $E =$ effectiveness of treatment measured in time. To adjust for quality of life, when the quantity does not change, the concept of utility is used. Utility is the value placed on time in a particular state of health. Perfect health would be assigned a utility value of 1.0 and death a value of 0.0. When utility, or the time × the utility value, is added, the equation becomes $\Delta C/\Delta U$ where $\Delta U = U_2 - U_1$. For example, a therapy that does not improve survival but increases utility by 10% will increase $U$ by (1 year) × (0.10) = 0.1 year. If this treatment costs an additional $10,000/year, then the cost-utility ratio is:

$$\Delta C = C_2 - C_1 = \$10,000 = \$100,000/\text{QALY}.\quad \Delta U = U_2 - U_1 = 0.10$$

Chemotherapy with cisplatin (cost saving) to C$8000 (cost saving) to C$20,000 (costs more than supportive care) for each additional year of life.44 Chemotherapy with cisplatin and vinorelbine compared to vinorelbine alone or cisplatin and vindesine added substantial clinical benefit45 at a reasonable cost effectiveness of C$15,000 to C$17,000/LY.46 Given the benefit and low cost of the drugs, vinorelbine and cisplatin compared to best supportive care would give results similar to those of Jaakimainen and colleagues.44 Evans and colleagues47 used decision analysis to show that chemotherapy in combination with radiation and/or surgery for stage IIIA or IIIB disease in comparison to treatment without chemotherapy would improve survival at a cost of C$3348 to C$14,958 per year of life saved. The model showed benefit at a reasonable cost under all situations of reasonable clinical efficacy. The chemotherapy treatments fit existing monetary guidelines for use.48,49

A trial of fluorouracil-based chemotherapy for gastrointestinal cancer patients randomized to first-line chemotherapy versus best supportive care, which could include later chemotherapy for symptom control, showed benefit at acceptable cost-effectiveness ratios.50 For the whole group, chemotherapy enhanced survival by about 5 months at a cost of about $20,000/LY gained, within accepted bounds.51 For subsets of types of cancer, such as gastric cancer, the treatment was effective at a reasonable cost. For most other subsets, the patient numbers were too small to draw meaningful conclusions about either clinical effect or cost effectiveness.

In a metastatic prostate cancer study, mitoxantrone added a clinical benefit in terms of pain relief and symptom control in
23 of 80 patients, lasting for 6 months more than prednisone alone, but did not alter survival when compared to prednisone alone. Although initial drug costs were higher, total disease costs were lower in the group that received mitoxantrone as initial treatment, so good chemotherapy palliation could be accomplished at no additional cost to society. Total androgen blockade produced small clinical benefit at an acceptable cost to society compared to single androgen blockade.

There have been no studies on the effectiveness or cost-effectiveness of chemotherapy for metastatic breast cancer compared to best supportive care. Hospitalization accounts for the majority of costs, while chemotherapy has been a relatively trivial cost in the United Kingdom. High-dose chemotherapy is commonly used for incurable metastatic disease, and in the one randomized controlled trial, it doubled overall survival from 10.4 to 20.8 months but did not produce a long-term survival plateau. In the only available study of comparative treatment, Hillner and associates compared best standard chemotherapy to high-dose chemotherapy with a stem-cell transplant. High-dose chemotherapy added about 6 months at a cost-effectiveness ratio of $116,000/LY gained, outside the bounds of accepted treatments. Of interest, drug costs for most breast cancer patients amount to less than 10% of the total cost.

Sometimes, highly expensive chemotherapy can be a "good value" for society if it gains substantial amounts of time, or if the comparative treatment is also expensive. Chemotherapy for acute myelogenous leukemia costs more than supportive care, but was effective enough to gain months or years compared to certain death, so the cost-effectiveness ratio was acceptable. Allogenic transplant was even more expensive than usual second-line chemotherapy, but the transplant survival

<tr>
<td>Lung cancer</td>
<td>Chemotherapy gained 8–13 weeks compared to best supportive care. Chemotherapy generally saved money for the province of Ontario, from a savings of $8000 to an additional cost of $20,000 depending on assumptions. Similar results were found for vinorelbine and cisplatin.</td>
</tr>
<tr>
<td>Combined modality including chemotherapy vs. radiation or surgery for stage III non-small-cell lung cancer.</td>
<td>Chemotherapy in combination with radiation or surgery adds clinical benefit; for chemotherapy plus radiation, 1- and 5-year survival rates are increased from 40% to 54% and from 6% to 17%, respectively. The addition of chemotherapy to IIIB patients added cost of $15,866, and addition of chemotherapy to IIIB patients added $8912. The cost per year of life gained was well within accepted bounds at $3348 to $14,958 CAN.</td>
</tr>
<tr>
<td>Alternating chemotherapy for small-cell lung cancer</td>
<td>The alternating chemotherapy arm cost more, but because it was more effective, the marginal cost effectiveness was only $4560/year of life.</td>
</tr>
<tr>
<td>Gastrointestinal cancer</td>
<td>Chemotherapy added 5 months median survival if given early rather than late, with symptom palliation for 4 months. The additional cost of about $20,000 per life year was within accepted bounds.</td>
</tr>
<tr>
<td>Prostate cancer</td>
<td>Mitoxantrone did not improve survival but did improve quality of life as measured by several indices, and the mitoxantrone strategy cost less than prednisone supportive care.</td>
</tr>
<tr>
<td>Breast cancer</td>
<td>High-dose chemotherapy added 6 months at a cost of $58,000, or $16,000 per life year; this is palliative care because this treatment has not been shown to be curative.</td>
</tr>
<tr>
<td>Other</td>
<td>Chemotherapy, compared to supportive care, added additional cost, but the cost effectiveness was $18,000/life year, within acceptable limits.</td>
</tr>
</tbody>
</table>
benefit of 48% versus 21% at 5 years was sufficient to offset higher costs of treatment and make the cost-effectiveness ratio about $18,000/LY.\textsuperscript{58}

The less expensive the setting, the less costly the intervention, as shown in Table 22–6. Home opioid infusions had lower total costs due to lower hospital costs despite higher drug equipment and nursing costs.\textsuperscript{59} Outpatient administration of chemotherapy was less expensive than inpatient administration.\textsuperscript{60} Home chemotherapy compared to outpatient chemotherapy was accepted well, with only two of 424 patients electing to discontinue home treatment; it was safe and no more costly, with an average cost of $50 as compared to $116 in the hospital and equal total costs.\textsuperscript{61}

Disease-management strategies have shown some modest improvements, with better quality of care, less cost, and high patient satisfaction. The available studies are shown in Table 22–7.

Coordinated care may be one of the most successful disease-management strategies. The Medicare Hospice Benefit requires nurse coordination, team management, easy access to low per diem hospital beds for respite or temporary care, and expanded drug coverage.\textsuperscript{62,63} Adding a nurse coordinator for terminally ill patients in England did not change any disease outcomes: patients still died, and most still had some unrelied symptoms; however, patient and family satisfaction was helped slightly.\textsuperscript{64} Total costs were reduced from £8814 to £4414 due to decreased hospital days, for a cost savings of 41% in almost all conditions. Home nursing care was associated with more patients dying at home.\textsuperscript{65}

One center did a pain-management intervention with enhanced institutional education programs, a highly visible respected consultative team, and a pain-resource center for nurses and families. This was associated with a decrease in admissions and readmissions for pain control and marked cost savings.\textsuperscript{66} The study was not randomized and could not account for other significant changes, such as the growth of managed care with restricted admission policies. However, the conclusion must be that this is better pain management and better medical care and probably saves money.\textsuperscript{67}

Teaching staff about choices for intensive care unit (ICU) use can improve economic outcomes. In one setting, an ethicist in the surgical ICU addressed the issues of patient choice about dying and the ethics of futile care. This was associated with a decrease in length of stay from 28 to 16 days, and a decrease in surgical intensive care days from 2028 to 1003, far greater than observed in other parts of the hospital. Cost savings were estimated at $1.8 million.\textsuperscript{68} In a similar project, Dowdy and colleagues\textsuperscript{69} did proactive ethics consultations for all mechanically ventilated patients beyond 4 days and showed improved length of stay (less use of the ICU, either by discontinuing futile care or transferring the patient to lesser-intensity units) and a decrease in costs.

Clinical practice guidelines for supportive care may decrease costs, but formal data have not been published.\textsuperscript{65} While there have been significant anecdotal data and clinical opinion that hospice provides improved quality and decreased cost, the available data do not show that hospice improves care or saves money, as shown in Table 22–8.\textsuperscript{63,70,71} A

</tbody>
</table>
large, randomized controlled trial of hospice versus standard care showed that hospice did not improve quality of care by any measured benchmark (pain, ability to perform activities of daily living). Patients still used many hospital days (48 for controls, and 51 for hospice), but more of the hospice patients were hospitalized on the hospice unit. There was no difference in diagnostic procedures or total costs (about $15,000 per patient).

More recent data suggest that hospice care can be cost saving. Smith and colleagues and Brumley and colleagues demonstrated that integrating palliative care into a curative practice model earlier in a disease trajectory improved patient satisfaction while decreasing needs of acute care and lowering health care costs. In the 1992 Medicare files, those cancer patients who elected hospice cost less than those who did not elect hospice. For those who enrolled in hospice in the last month of life, typically over half of Medicare hospice patients, Medicare saved $1.65 for each $1 spent. However, those who elected hospice tended to use more resources in the months from diagnosis until about 3 months before death, so the total disease-management savings were close to zero. Similar findings were reported previously.

Hospice may actually not save total disease-management costs but just shift them to costs not captured by our current accounting systems. In our own study of Medicare hospice use in Virginia, total disease-management costs were actually higher for those who eventually elected hospice. Those who elect hospice tend to have resources to absorb more home care costs, more out-of-pocket drug costs, etc. The data are consistent with an affluent group of patients using all of the resources needed for treatment, then using hospice resources in addition. There are no published data on whether the medically underserved use hospice, whether they will accept its philosophy, or how much they will cost the system.

Database studies have shown similar results. In a retrospective study of 12,000 patients at 40 centers, Aiken found that hospice patients were more likely to receive home nursing care and to spend less time in the hospital than conventional care patients. Of the three models of care evaluated, conventional care was the least expensive when overall disease-management costs were calculated, but hospital-based hospice ($2270) and home care hospice ($2657) were less expensive than conventional care ($6100) in the last month of life.

Advanced directives, such as “do-not-resuscitate” (DNR) orders, have been advocated to allow patients to make autonomous choices about their care at the end of life and possibly to reduce costs by preventing futile care. However, as reviewed by Emanuel and Emanuel,70,76 there has been no cost saving associated with the use of either advanced directives or DNR orders (Table 22–9). These findings have been confirmed in the more recent SUPPORT study.77

End-of-life or advanced planning is clearly a part of palliative care and care of the dying. Levinsky 22 has questioned whether end-of-life planning has become an economic strategy as much as a way to respect a patient’s wishes: “Confusion between advance planning as a method to find out what the patient wants and advance planning as a mechanism to reduce medical care and thereby contain costs represents a clear danger to the goals of informed consent and autonomy for patients.” In a randomized study of 204 patients with life-threatening diseases, it was found that in those who executed an advance directive, there was no significant positive or negative effect on well-being, health status, medical treatments, or medical treatment charges.78

### Nursing Issues

Nursing needs to continue to advocate for this population while supporting effective quality care, and fair utilization of resources must be frequently assessed. For example, the use of advanced technology, especially expensive diagnostic tests, may be accepted as routine in an acute care hospital, even though it is costly, unnecessary, and not consistent with the goals of palliative care. Consider the following examples.

1. An 82-year-old man with end-stage chronic obstructive pulmonary disease requests removal from a respirator and comfort measures only. He is deemed competent, yet it is questionable if he will be able to survive off the respirator. His wishes are followed, and he is extubated. While adamantly refusing any discussion regarding reintubation, he continues to have arterial blood gases sampled every 2 to 3 hours around the clock. Clearly, use of such sampling is academic because the patient refuses reintubation. Sampling of arterial blood gases is costly and painful because the patient refuses reintubation. Sampling of arterial blood gases is costly and painful because the patient refuses reintubation.
2. A 32-year-old man with widely metastatic colon cancer arrives in your facility with a bowel obstruction related to his disease. He has been in the local hospice program. After evaluation, his prognosis is confirmed as approximately 6 weeks. He has a nasogastric tube placed to relieve persistent nausea, vomiting, and abdominal discomfort. After 4 days of decompression, the surgeon offers to place a gastrostomy tube for drainage and decompression. While the surgery will be costly, placement of the gastrostomy tube meets the goals of both comfort and providing the patient with the ability to return home.

3. A 29-year-old woman with acquired immunodeficiency syndrome is admitted for severe debilitating neuropathic pain, unresponsive to typical analgesic agents. The patient is losing her ability to ambulate due to the pain. She is given a trial of epidural opioids with local anesthetics, which offer almost complete pain relief. An intrathecally implanted pump, at a cost of several thousand dollars, is placed. While the initial cost is staggering, the long-term benefits are considerable, including measurable improved functional status, decreased occurrence of depression, decrease in required skilled and nonskilled nursing care hours, decreased opportunistic infection, and improved quality of life for both the patient and her significant others.

4. A 60-year-old woman with multiple myeloma is admitted with an adjusted serum calcium level of 179 mg/dL. The myeloma is now progressing and refractory to therapy. Intravenous fluids, diuretics, biphosphates, and calcitonin are administered, and serum calcium is drawn every 12 hours. The patient's disease is irreversible. The present interventions will perhaps delay an inevitable outcome, but they will cost thousands of dollars, while not improving the patient's quality of life, and may potentially cause discomfort.

This process of reassessment and recognition should be fostered through education and role modeling and should begin in the very basic nursing courses. It must be integrated throughout the longitudinal nursing curriculum, as patients dealing with end-of-life disease processes exist in almost all health care settings. It is imperative that outcomes research accompanies education to ensure the best and most cost-efficient palliative care available.

5. A 36-year-old man with a self-inflicted gunshot wound arrives in your emergency room. The neurosurgical team determines the injury to the brain is devastating and that the prognosis is grave. The family requests all measures to keep him alive “no matter what.” They demand ongoing ventilator and nutritional support. What role should the nurse take in this situation? What options might the health care team have, should the family be unwilling to understand the illness trajectory of their relative? What role should the hospital take in this matter? How will you advocate?

6. A 68-year-old previously healthy woman has suffered a traumatic subdural hematoma, with significant brain damage. She only opens her eyes to verbal stimuli and does not follow commands 2 weeks after her injury. She has been receiving NG feedings. The patient has a living will that clearly states no artificial nutrition if her condition becomes irreversible. The social worker informs the medical team that she cannot place this patient in a nursing home unless she becomes “skilled,” which a PEG feeding tube would accomplish. What is your role? The hospital could lose considerable revenue if the patient is not placed in a nursing home? What presently happens in your facility? What role would your ethics and risk management play in this case?

Summary

Economic outcomes are increasingly important for all types of health care, including palliative care. The few studies show substantial opportunities for improvement by using disease-management strategies. Chemotherapy for some cancers (non-small-cell lung cancer, prostate cancer, and gastrointestinal cancer) is reasonably effective and has acceptable cost-effectiveness ratios; this does not apply to any regimen that has not been formally evaluated. Coordination of palliative care shows no major clinical benefit but does show major cost savings. Directed, ethically motivated interventions about futile care appear to produce significant cost savings. The use of advance directives or hospice care may be good medical care but has not been shown to produce major economic benefit.

The cost of care is rising due to the increasing age of the population, more cancer cases and chronic diseases, increased demand for treatment, and new and expensive technologies. Our limited resources must be rationed wisely so that we can provide both curative and palliative care. The ethical implications of using economic and management outcomes rather than traditional health outcomes include shifting emphasis from helping at all cost to helping at a cost society can afford, as well as how much society is willing to pay; the value of care to the dying versus those with curable illnesses; and tolerance of suboptimal care.

The outcomes of palliative care do not differ from those of other cancer treatment, from the perspective of economics or health service research. For treatment to be justified, there must be some demonstrable improvement in disease-free or overall survival, toxicity, quality of life, or cost effectiveness. Palliative care usually does not change survival, and it does not have a measurable cost-effectiveness ratio since it does not gain years of life. There may be little change in quality-adjusted life
years because the improvements in health state are too small to measure with current instruments or are lost in the impact of the disease.

Only a few studies have assessed the economic outcomes of palliative therapy. The major areas of interest include the following: (1) palliative chemotherapy versus best supportive care; (2) supportive care for cancer symptoms; (3) the process and structure of care; (4) follow up; and (5) hospice care. Palliative first-line chemotherapy for stage III and IV non-small-cell lung cancer, mitoxantrone for prostate cancer, and fluorouracil-based chemotherapy for gastrointestinal cancer have acceptable cost-effectiveness ratios. Supportive care effectiveness and cost for infections, nausea, and pain can be improved. Research outside of cancer is scant. Hospice care saves at best 3% of total care cost but gives care equal to nonhospice care. Coordination of palliative care will save 40% of costs but will not improve the clinical outcomes of dying patients.\(^3\) Nursing clearly has the ability to impact the care and cost for this population and should be in the forefront of these issues.\(^3\)

Hallmarks of palliative care are skilled assessment and rapid evaluation and management of symptoms that impact negatively on patient and family quality of life. This chapter addresses select syndromes that unless recognized and treated promptly will cause unnecessary suffering for the patient and family.

SUPERIOR VENA CAVAL OBSTRUCTION

CASE STUDY 1
Mr. W, a Patient with Small-Cell Lung Cancer

Mr. W, a 72-year-old retired Army colonel, recently had a central-venous access device placed in preparation for chemotherapy for small-cell lung cancer. He is also receiving concurrent radiation therapy. You meet Mr. W and his wife for the first time in the outpatient oncology clinic. They are nervous about chemotherapy, but he says "I'll do anything to beat this thing." His wife tells you in his presence, "I think his arm has swelled some since they put that catheter in. His face seems 'fuller' in the morning when he wakes up and he looks different. Is that normal?" Mr. W says, "Oh honey, you worry about everything," and turns to you, winks, and says, "There's nothing wrong, right?" He then asks his wife to leave the room so he can talk to you privately. He says "I want to know what I'm facing, but I don't want my wife to worry."

Key Points
- Superior vena caval obstruction can cause distressing symptoms that are amenable to palliation.
- The common presenting symptoms are dyspnea, facial swelling, and feeling of fullness in the head.
The patient’s swollen and distorted facial features can be highly upsetting to the patient and family.

The diagnosis of vena caval syndrome can usually be made on clinical grounds.

Definition

Superior vena caval obstruction (SVCO) is a disorder produced by obstruction of blood flow in the superior vena cava, which results in impairment of blood flow through the superior vena cava into the right atrium. Severity of the syndrome depends on rapidity of onset, location of the obstruction, and whether or not the obstruction is partial or complete. Obstruction may occur acutely or gradually, and symptoms may be severe and debilitating.1,2

Epidemiology

The patient most likely to experience SVCO is a 50- to 70-year-old man with a primary or metastatic tumor of the mediastinum. More than 90% of SVCO cases are due to cancer, most commonly, endobronchial tumors.3,4 In the majority of patients, the presence of SVCO is not a poor prognostic indicator of survival.2 The prognosis of patients with SVCO strongly correlates with the prognosis of underlying disease.

Two types of obstruction1 may cause SVCO: (1) intrinsic obstruction, and (2) extrinsic obstruction. Intrinsic obstruction is usually caused by primary tracheal malignancies that invade the airway epithelium, that is, squamous cell carcinoma and adenoid cystic carcinoma, as well as other benign and malignant tumors. Extrinsic obstruction occurs when airways are surrounded and compressed by external tumors or enlarged lymph nodes, that is, lymphoma, and locally advanced thyroid, lung, or esophageal cancers. Obstruction may be caused by a tumor arising in the right main or upper-lobe bronchus or by large-volume lymphadenopathy in the right paratracheal or precarinal lymph node chains.6

Thrombosis of the superior vena cava (SVC) is also associated with insertion of indwelling intracaval catheters and central-venous access devices, which are thought to damage the intima of vessels. Both adults and children may experience thrombosis of the SVC. More than compression or tumor, thrombosis is likely to cause acute and complete obstruction of the SVC.7 Cancer patients are also at greater risk of experiencing hypercoagulopathies, which increase the risk of experiencing thrombosis and SVCO. Other less common nonmalignant causes associated with SVCO are mediastinal fibrosis from histoplasmosis and iatrogenic complications from cardiovascular surgery.5

Pathophysiology

The superior vena cava is located in the rigid thoracic cavity and is surrounded by a number of structures, including the sternum, trachea, right bronchus, aorta, pulmonary artery, and several lymph node chains. There is little room for structures to move or expand within this cavity, thus the superior vena cava is vulnerable to any space-occupying lesion in its vicinity. Venous drainage from the head, neck, upper extremities, and upper thorax collects in the SVC on its way to the right atrium. The SVC has a thin wall, and normally, blood flows through the vessel under low pressure. When the vessel is compressed, blood flow is slowed, fluid pressure is increased, and occlusion may occur.9

When venous collateral circulation has time to develop, the symptoms of SVCO are likely to develop insidiously.10 The presence of collateral circulation, tumor growth rate, and extent and location of the blockage are factors in determining how rapidly SVCO develops.11

Signs and Symptoms

The onset of symptoms is often insidious. Patients may report subtle signs that include venous engorgement in the morning hours after awakening from sleep, difficulty removing rings from fingers, and an increase in symptoms when bending forward or stooping, all of which may not be noticed initially.9,12 The most common symptom of the syndrome is dyspnea.19,12,13 Swelling of the neck and face is seen in 50% of patients. Other common symptoms are cough (54%), arm swelling (18%), chest pain (15%), and dysphagia (9%).7 Physical findings include venous distention of the neck (66%), venous distention of the chest wall (54%), facial edema (46%), plethora, a very ruddy facial complexion (19%), and cyanosis (19%). Patients may experience tachypnea, hoarseness, nasal stuffiness, periorbital edema, redness and edema of the conjunctivae, and, rarely, paralyzed vocal cord.16

In severe or rapid cases, where collateral circulation has not yet made accommodation for increased blood flow, symptoms may be immediately life-threatening. Patients may experience orthopnea, stridor, respiratory distress, headache, visual disturbances, dizziness, syncope, lethargy, and irritability. As the condition further progresses, significant mental status changes occur, including stupor, coma, seizures, and, ultimately, death.17

Diagnostic Procedures

Plain chest x-ray films are the least invasive diagnostic modality.7 Computed tomography (CT) is the most widely available and used modality to elucidate the location, extent of obstruction or stenosis, presence and extent of thrombus formation, and status of collateral circulation,18–21 and can be performed unless the patient is so debilitated that no further treatment is indicated or desired by the patient.21 Magnetic resonance imaging (MRI) is another diagnostic tool that can confirm the diagnosis of SVC21 and distinguish between tumor mass or thrombosis.

Palliation of Symptoms

The effectiveness of palliation of symptoms of SVCO in patients who have persistent or recurrent small-cell lung cancer
(SCLC) has been reviewed. Chemotherapy or mediastinal radiation therapy were found to be very effective as initial treatment for patients who have SCLC and SVCO at first presentation, as well as in those with recurrent or persistent disease. It was recommended that radiation therapy should be used in those patients who have been previously treated with chemotherapy. However, due to side effects, large fractions should be avoided. When comparing the treatment modalities used to treat SVCO, including chemotherapy alone, chemotherapy and radiation therapy, and radiation therapy alone, none has proved superior. Adverse prognostic indicators are dysphagia, hoarseness, and stridor.

**SVC Stenting**

Current American College of Chest Physicians (ACCP) guidelines state that lung cancer patients with symptomatic SVCO can be treated with radiation therapy, insertion of an SVC stent, or both. More recent evidence indicates that symptomatic patients may possibly be better treated initially by SVC stenting. Although there are no controlled studies comparing radiation therapy with SVC stenting, several reviews and non-randomized studies indicate that this procedure can relieve edema, promote improved superficial collateral vein drainage, and improve neurological impairment. It can also relieve dyspnea, provide greater relief of obstruction, create few or minor complications, and allow for the full use of chemotherapy and radiation therapy, thus providing more rapid relief in a higher proportion of patients. Complications associated with SVC stenting procedures include bleeding due to anticoagulation, arrhythmia, septic episodes, thrombosis, fibrosis, and migration of the stent.

**Thrombolytic Therapies**

Thrombolytic therapy has often been successful in the lysing of SVC thrombi. Another alternative, percutaneous angioplasty with or without thrombolitics, may open SVC obstructions. Documented thrombi may be treated with tissue plasminogen activators (TPS).

**Drug Therapy**

Steroids have been one of the standard therapies for treatment of SVCO in spite of the lack of evidence to support their use. Prednisone and methylprednisolone have both been used to reduce inflammation in the treatment of SVCO. Prednisone dosages range from 5 to 60 mg orally once a day or are given in a divided dosage schedule of either twice daily or four times daily. The drug is then tapered over 2 weeks as symptoms resolve. Methylprednisolone may be given in an initial IV dosage of 125 to 250 mg. The maintenance dose is 0.5–1 mg/kg/dose every 6 hours for up to 5 days.

Diuretics, such as furosemide, may be given to promote diuresis, thus decreasing venous return to the heart, which reduces pressure in the SVC. In general, a 20- to 80-mg dose is given once, then repeated every 6 to 8 hours as necessary, and may be increased by 20 to 40 mg per dose if necessary. The dose should be individualized to the requirements of each patient.

**Nursing Management**

The primary nursing goals are to identify patients at risk for developing SVC syndrome, to recognize the syndrome if it does occur, and to relieve dyspnea and other symptoms. Reduction of anxiety is an important nursing goal. The patient and family may experience significant distress not only because of physical symptoms experienced but also because of an altered physical appearance, including a ruddy, swollen, distorted face and neck.

The nurse monitors the patient for side effects of treatment and provides symptom management. For example, if the patient is receiving radiation therapy, be alert for signs of dyspnea (which may indicate presence of tracheal edema), pneumonitis, dysphagia, pharyngitis, esophagitis, leukopenia, anemia, skin changes, and fatigue. If the patient is receiving chemotherapy, be alert for signs of stomatitis, nausea and vomiting, fatigue, leukopenia, anemia, and thrombocytopenia. If the patient is receiving steroid therapy, educate the patient and family about the potential for developing proximal muscle weakness, mood swings, insomnia, oral candida, and hyperglycemia. Aspects of palliative care always of primary importance are early recognition and management of symptoms, educating the patient and family about these symptoms and what to report, and providing reassurance that these symptoms, if they occur, will be controlled.

**PLEURAL EFFUSION**

**CASE STUDY 2**

**Ms. B, a Patient with Breast Cancer**

Ms. B, a 42-year-old divorced woman, has been living with breast cancer for the last 5 years. She has received numerous therapies, none of which has halted the progression of her disease, but she wants to continue with chemotherapy. She now has widely metastatic disease in her bone, liver, and both lungs. In the clinic, you are preparing her chemotherapy as she tells you that over the past several weeks she has been feeling more fatigued and has no appetite. She has also been feeling more short of breath, which first occurred when she was walking but now is present all the time. She complains of feeling pressure and pain in her chest and especially when breathing in a deep breath. “I... know... it’s the... cancer taking... over. I’m losing... the battle,” she tells you breathlessly. Her pulse is rapid and her respirations are 24 a minute. You notice that she is using her accessory breathing muscles to breathe. You listen to her lungs and she has decreased...
breath sounds on the left side; she also has decreased diaphragmatic excursion on her left side. When you percuss the lungs, you also notice dullness on the left side.

- **Key Points**
  - The treatment of pleural effusion is palliative and symptomatic.
  - The treatment approach depends on clinical circumstances, the patient's general condition, and nearness to death.
  - Preemptive pain management is a critical nursing function when patients undergo invasive procedures.

**Definition**

Pleural effusion is defined as a disparity between secretion and absorption of fluid in the pleural space secondary to increased secretion, impaired absorption, or both, resulting in excessive fluid collection.

**Epidemiology**

More than 150,000 pleural effusions (PE) are diagnosed each year in the United States. Parapneumonic disease is the most common cause of pleural effusions, followed by malignant disease. Bronchogenic, breast, and lymphoma malignancies account for 75% of all malignant pleural effusions (MPE), followed by ovarian cancer and gastric cancer, in order of descending frequency. Almost half of patients with metastatic disease will experience a pleural effusion sometime during the course of their disease.

Pleural effusions occur in 7% to 27% of hospitalized human immunodeficiency virus (HIV) patients. The three leading causes of PE in those with HIV disease are parapneumonic infection, pulmonary Kaposi's sarcoma (KS), and tuberculosis. The overall mortality rate associated with pleural effusion in HIV patients is 10% to 40%. Unfortunately, the presence of malignant pleural effusion is usually associated with widespread disease and poor clinical prognosis, particularly in those with malignancy or AIDS. The overall mean survival for cancer patients who have MPE is 4 to 12 months. Lung cancer patients usually die within 2 to 3 months, breast cancer patients within 7 to 15 months, and ovarian cancer patients within 9 months. The mean survival period of those with pulmonary KS and MPE is 2 to 10 months; for those who have lymphoma and MPE, it is about 9 months. Nearly all patients who have malignant pleural effusion are appropriate candidates for hospice care.

**Pathophysiology**

Each lung is covered with a serous membrane called the pleura. A closed cavity is located between the pleura and the surface of each lung, called the pleural cavity. Under normal circumstances, it is bathed with 10 to 120 mL of almost protein-free fluid that continuously flows across the pleural membrane. The fluid moves from the systemic circulation into the pleural cavity and then into the pulmonary circulation. Osmotic and hydrostatic pressure act to ensure that equilibrium is maintained between absorption and production of fluid in the pleural space. When this equilibrium is disturbed, fluid can accumulate in the pleural cavity.

A number of factors may disturb this equilibrium:

1. Metastatic implants or inflammation that cause increased hydrostatic pressure in the pulmonary circulation;
2. Inflammatory processes that increase capillary permeability and increase oncotic fluid pressure in the pleural space;
3. Hypoalbuminemia that decreases systemic oncotic pressure;
4. Tumor obstruction or lung damage that creates increased intrapleural pressure;
5. Impaired absorption of lymph when channels are blocked by tumor; and
6. Increased vascular permeability caused by growth factors expressed by tumor cells.

Patients with large pleural effusions have demonstrated left-ventricular diastolic collapse and cardiac tamponade, which resolved with thoracentesis.

**Diagnostic Procedures**

A chest x-ray will usually establish the presence of the pleural effusion and should also differentiate the presence of free versus loculated pleural fluid. CT can show pleural or lung masses, adenopathy, pulmonary abnormalities, such as infiltrates or atelectasis, or distant disease. Chest ultrasound may differentiate between pleural fluid and pleural-thickening disease.

In some cases, once evidence of the effusion has been established and obvious nonmalignant causes have been ruled out, a diagnostic thoracentesis may be helpful in establishing the diagnosis. Sonographic guidance can avoid problems associated with performing “blind” thoracentesis.

**Signs and Symptoms**

Dyspnea is the most common symptom of pleural effusion and occurs in about 75% of patients. Its onset may be insidious or abrupt and depends on how rapidly the fluid accumulates. It is almost always related to collapse of the lung from the increase of pleural fluid pressure on the lung.

The patient's inability to expand the lung leads initially to complaints of exertional dyspnea. As the effusion increases in volume, resting dyspnea, orthopnea, and tachypnea develop. The patient may complain of a dry, nonproductive cough, and an aching pain or heaviness in the chest. Pain is often described as dull or pleuritic in character. Generalized systemic symptoms associated with advanced disease may also be present: malaise, anorexia, and fatigue.

Physical examination reveals the presence of dullness to percussion of the affected hemithorax, decreased breath sounds, egophony, decreased vocal fremitus, whispered pectoriloquy, and decreased or no diaphragmatic excursion. A large effusion may cause mediastinal shift to the side of the effusion; tracheal deviation may be present. Cyanosis and plethora, a ruddy facial complexion that occurs with partial caval obstruction, may also be present.
Medical and Nursing Management

Overall medical management of malignant pleural effusion depends on multiple factors. The history of the primary tumor, prior patient history and response to therapy, extent of disease and overall medical condition, goals of care, and severity of symptom distress. In some cases, systemic therapy, hormonal therapy, or mediastinal radiation therapy may provide control of pleural effusions. Symptomatic management of symptoms with pharmacotherapy includes the use of opioids to manage both pain and dyspnea, as well as anxiolytics to control concomitant anxiety.

If the patient is to have a chest tube placed or other invasive procedures to drain the fluid or to prevent fluid reaccumulation, the nurse must aggressively manage the patient’s pain and anxiety. Educating the patient about what to expect, staying with them during the procedure and medicating them preemptively are important aspects of palliative nursing care. Use of patient-controlled analgesia (PCA) for pain management is appropriate. Unfortunately, pain assessment and management is frequently not recognized as a priority when patients undergo these procedures.

Thoracentesis Alone

Thoracentesis has been shown to relieve dyspnea associated with large pleural effusions. When thoracentesis is undertaken, relief of symptoms may rapidly occur, but fluid reaccumulates quickly, usually within 3 to 4 days, and in 97% of patients, within 30 days. The decision to perform repeated thoracenteses should be tempered by the knowledge that risks include empyema, pneumothorax, trapped lung from inadequate drainage and/or loculated fluid, and the possibility of increasing malnutrition as a result of the removal of large amounts of protein-rich effusion fluid.

Repeated thoracenteses rarely provide lasting control of malignant effusions. There are no studies that compare repeated thoracenteses to other management approaches. Instead of a second thoracentesis, a thoracostomy with pleurodesis may be considered. It can be used to reduce adhesions, draw off fluid, and initiate drainage, all at the same time.

Tube Thoracostomy and Pleurodesis

Palliative treatment, especially for those with a life expectancy of months rather than weeks, is best accomplished by performing closed-tube thoracoscopy, using imaging guidance with smaller bore tubes. The goal of this therapy is to drain the pleural cavity completely, expand the lung fully, and then to install the chemical agent into the pleural cavity. However, if there is a large effusion, only 1000 mL to 1500 mL should be drained initially. Too-rapid drainage of a large volume of fluid can cause reexpansion pulmonary edema, and some patients have developed large hydropneumothoraces following rapid evacuation of fluid. The thoracoscopy tube should then be clamped for 30 to 60 minutes. Approximately 1000 mL can be drained every hour until the chest is completely empty, but a slow rate of drainage is recommended. The chest tube is then connected to a closed-drainage device. To prevent re-expansion pulmonary edema, water-seal drainage alone and intermittent tube clamping should be used to allow fluid to drain slowly.

Complications of chest tube placement include bleeding and development of pneumothorax, which occurs when fluid is rapidly removed in patients who have an underlying noncompliant lung. Patients who have chest tubes inserted should receive intrapleural bupivacaine or epidural and intravenous (IV) conscious sedation, as the procedure can be moderately to severely painful.

Pleurodesis

Chest radiography is used to monitor the position of the thoracostomy tube after thoracostomy is completed. It is thought that tube irrigation of the pleural cavity may encourage loculations, which can lessen the effectiveness of potential sclerosing agents. Current evidence indicates that it is not necessary to wait for drainage to fall below a certain level, and that the sclerosing agent can be injected as soon as the lung is fully reexpanded. If the lung fails to expand and there is no evidence of obstruction or noncompliant lung, additional chest tube placement may be considered. Fibrinolysis with urokinase or streptokinase may improve drainage in those cases where fluid is still present or is thick or gelatinous. Intrapleural instillation of urokinase 100,000 units in 100-mL 0.9% saline can be attempted, and the chest tube clamped for 6 hours, with suction then being resumed for 24 hours. Once the pleural fluid has been drained and the lung is fully expanded, pleurodesis may be initiated. This can usually take place the day after chest tube insertion.

The purpose of pleurodesis is to administer agents that cause inflammation and subsequent fibrosis into the pleural cavity to produce long-term adhesion of the visceral and parietal pleural surfaces. The goal of this procedure is to prevent reaccumulation of pleural fluid. Various sclerosing agents are used to treat MPE. They include bleomycin, doxycycline, and sterilized asbestos-free talc. The overall response rate to chemical pleurodesis is 64%.

Pleuroperitoneal Shunt

This procedure is useful for patients who have refractory MPE despite sclerotherapy. Two catheters are connected by a pump to a chamber between the pleural cavity and the peritoneal cavity. Manually pushing the pumping chamber moves fluid from the pleural cavity to the peritoneal cavity. Releasing the compression moves the fluid from the pleural cavity into the chamber.

The major advantage of this device is that it can be used on an outpatient basis and allows the patient to remain at home. Its disadvantages include obstruction risk, infection, tumor seeding, general anesthesia is needed for placement, and the
device requires motivation and ability on the part of the patient to operate it. Most patients with advanced disease are unable to physically overcome the positive peritoneal pressure required to pump the device. Pumping is required hundreds of times a day, and therefore this device is not likely to be useful in those who are close to death.90

Pleurectomy

Surgical stripping of the parietal pleura, with or without lung decortication (if the underlying lung is trapped), is more than 90% effective, but it has a high complication rate67,72 and should be reserved for only those who have a reasonable life expectancy and physical reserve to withstand surgery.29,32 Video-assisted thoracoscopic surgery (VATS) and pleurectomy have been performed successfully in small selected groups of patients.91 However, it is likely to be an inappropriate choice in the palliative care patient at end of life.

Indwelling Pleural Catheters

Indwelling pleural catheters can be placed under local anesthesia.65 Those who meet criteria for ambulatory therapy, that is, those with symptomatic, unilateral effusions, and who have a reasonable performance status may benefit from this therapy. It has been suggested that tunneled pleural catheters may permit long-term drainage and control of MPE in more than 80 to 90% of patients.36,92,93 These catheters can be used to treat trapped lungs and large locules. Spontaneous pleurodesis may occur in up to 40% of patients.

Small-bore tubes attached to gravity drainage bags or vacuum drainage have been reported to be successful on an outpatient basis.47 Rare complications include tumor seeding, obstruction, infection, cellulitis of tract site, and pain during drainage. If spontaneous pleurodesis does not occur, then continuing drainage may present management challenges. This treatment offers the potential for better quality of life and reduction in overall health care costs.

Subcutaneous Access Ports

In this procedure a fenestrated catheter is placed in the pleural cavity. It can be accessed for repeated drainage without risk of pneumothorax or hemothorax.47 Complications include occlusion, kinking, and wound infection.

Nursing Management

Dyspnea and anxiety are primary symptoms experienced by the patient who has a pleural effusion. When invasive diagnostic procedures are being considered, these choices should be guided by the stage of disease, prognosis, the risk/benefit ratio of tests or interventions, pain-management considerations, and the desires of the patient and family.29 The nurse can educate the patient and family about each procedure, including its purpose, how it is carried out, how pain will be addressed, and possible side effects or complications that may occur. This not only allows for informed consent but also may help to reduce anxiety and thus decrease dyspnea.94 A variety of nonpharmacological techniques can relieve the patient’s dyspnea and pain and can be used in combination with opioids and anxiolytics, as well as concurrently with medical treatment. These approaches include positioning the patient to comfort, using relaxation techniques, and providing oxygenation as appropriate.94 Aggressive pain assessment and monitoring are particularly important for patients who receive invasive procedures.

PERICARDIAL EFFUSION

CASE STUDY 3
Mr. S, a Patient with Leukemia in Remission

Mr. S, a 28-year-old married man with a diagnosis of leukemia, has been in remission following a second induction therapy. His sperm had been banked before starting therapy, and he and his wife have a baby girl. He is now rehospitalized in blast crisis. When you ask his oncologist if end-of-life discussions have been held with the family, he tells you, “I’m pulling out all the stops on this one. He’s going on another clinical trial.” His wife draws you aside and says, “Don’t tell him that I told you this, but he’s been coughing a lot more at home lately, and I’ve noticed that he can’t seem to catch his breath. He won’t let me tell the doctor. I’m afraid and I don’t know what to do.” You begin your nursing assessment and notice that the patient is tachycardic and anxious. You try to listen to his heart but the sounds are very faint. You are concerned, but he says, “Let’s get this chemo going. I’ve got a daughter to get home to.”

Key Points
* Malignant pericardial effusions occur in less that 5% of patients with cancer, but the incidence may be nearer to 20% in patients with lung cancer.
* Effusions usually develop in patients with advanced disease and are usually a poor prognostic sign.
* The clinical features depend on the volume of pericardial fluid, the rate of accumulation of fluid, and the underlying cardiac function.
* Dyspnea is the most common presenting symptom.

Definition

A pericardial effusion is defined as an abnormal accumulation of fluid or tumor in the pericardial sac.95 Pericardial effusions can lead to life-threatening sequelae. They can be caused by malignancies and their treatment, and by nonmalignant conditions. Pericardial effusions can lead to cardiac tamponade, which, if not treated, will cause cardiovascular collapse and death.95
Epidemiology

Malignant disease is the most common cause of pericardial effusions.96 Pericardial effusion is most commonly associated with lung and breast cancer, leukemia, and lymphoma.96 Twenty-five percent to 50% of all patients who require surgical pericardial drainage have malignant pericardial involvement.96 Metastatic spread or local extension from esophageal tumors and from sarcomas, melanomas, and liver, gastric, and pancreatic cancers can also occur.97–100 Many pericardial effusions are asymptomatic and are discovered only on autopsy.101 Up to 40% of cancer patients who have a symptomatic pericardial effusion will have a benign cause of the effusion.37 Nonmalignant causes of pericardial effusions include pericarditis, congestive heart failure, uremia, myocardial infarction, and autoimmune disease, such as systemic lupus erythematosus. Other causes are infections, fungi, virus, tuberculosis, hypothyroidism, renal and hepatic failure, hypoalbuminemia, chest trauma, aneurysm, and complications of angiographic and central venous catheter procedures.102,103 A treatment-related cause of pericardial effusion is radiation therapy to the mediastinal area of more than 4000 cGy, which can lead to pericarditis and possible cardiac tamponade.99,104,105 The anthracycline-based chemotherapies, such as doxorubicin, can also cause pericardial effusions.106

Pathophysiology

The heart is covered by a thin sac called the pericardium. There are usually 15 to 50 mL of fluid between the pericardium and the heart itself.37 Pericardial fluid originates in lymphatic channels surrounding the heart and is reabsorbed and drained by the lymph system into the mediastinum and into the right side of the heart.10,11 This fluid minimizes friction, provides a barrier against inflammation, supports the chambers of the heart, and maintains the heart’s position in the chest against accelerational and gravitational forces.107–110 A pericardial effusion occurs when there is excessive fluid in this space. This fluid causes increased pressure to build in the pericardial sac, and the heart cannot fill or pump adequately. A pericardial effusion refers to the increased fluid or tumor in the pericardial sac. Cardiac tamponade is the physiological hemodynamic response of the heart to the effusion.9

Malignancies can cause effusions in the pericardial space by: (1) blocking lymph and blood drainage and preventing their resorption, (2) producing excess fluid in the space, (3) bleeding into the space, and (4) growing tumor into the space. The pericardial sac can hold up to 1800 mL of fluid before the heart begins to decompensate.111,112 Thus, volume of fluid and distensibility will affect the impact of effusion on intrapericardial pressure.

Cardiac tamponade occurs when the heart cannot beat effectively because of excess pressure being exerted on its muscle.99,102 As the pressure of fluid in the pericardial sac increases, the heart chambers are compressed. First, the right side of the heart, including the right atrium and right ventricle, is compressed. Less blood volume returns to the right side of the heart, thus increasing venous pressure. As the ventricles are further compressed, the heart cannot fill adequately, which leads to decreased stroke volume and cardiac output, and poor perfusion throughout the body. The body attempts to compensate by activating the adrenergic nervous system to keep the heart stimulated and its chambers filled with circulating blood volume. Heart rate increases, veins constrict, and the kidneys increase sodium and fluid retention. The heart ultimately is overwhelmed due to increased fluid, decreased filling, and decreased cardiac output, which leads to hypotension and circulatory collapse.90,113–115

Pericardial effusion can develop gradually over a period of weeks or months. The pericardium becomes more compliant, stretching to accommodate as much as 2 liters or more of fluid, with minimal effect on pericardial pressure. This is known as the “stress relaxation” phenomenon. Unfortunately, patients with chronic pericardial effusions may not exhibit physical signs of cardiac tamponade until compression of the heart and surrounding structures occurs, leading to sudden, life-threatening cardiac decompensation.113–115

Signs and Symptoms

Pericardial tamponade that results from metastatic disease has a gradual onset that may be chronic and insidious.9,107,114 Vague symptoms may be reported. Early in the decompensation process it may be difficult to differentiate symptoms of cardiac dysfunction from the effects seen in advancing cancer. The severity of symptoms is related to volume of the effusion, rate of accumulation, and the patient’s underlying cardiac function.10,99,111,116 Generally, rapid accumulation of fluid is associated with more severe cardiac tamponade. The most powerful predictor of the development of cardiac tamponade is the size of the pericardial effusion.117 Dyspnea is the most common presenting symptom.118,119 The patient may complain of the inability to catch his or her breath, which progresses from dyspnea on exertion to dyspnea at rest. In advanced stages, the individual may be able to speak only one word at a time. Chest heaviness, cough, and weakness are also symptoms.57 Pressure on adjacent structures, that is, the esophagus, trachea, and lung may increase.120 Tachycardia occurs as a response to decrease in cardiac output. A narrowing pulse pressure (difference between systolic and diastolic blood pressure) may be seen when blood backs up in the venous system, causing the systolic blood pressure to decrease and the diastolic blood pressure to increase.9,120 Compression of the mediastinal nerves may lead to cough, dysphagia, hoarseness, or hiccups.11 Increased venous pressure in the chest may lead to gastrointestinal (GI) complaints, such as nausea.121,122 Retrosternal chest pain that increases when the patient is supine and decreases when he is leaning forward may occur but is often not present.110,120 Engorged neck veins, hepatomegaly, edema, and increased diastolic blood pressure are late signs of effusion. Anxiety, confusion, restlessness, dizziness, lightheadedness, and agitation related to hypoxemia.
may be present as the process progresses. Poor cardiac output will lead to complaints of fatigue and weakness.

As the effusion increases and the heart begins to fail, symptoms worsen and dyspnea and orthopnea progress. Increasing venous congestion leads to peripheral edema. As cerebral perfusion worsens and hypoxemia increases, confusion increases. Ultimately, there is cardiovascular collapse, anuria, and decreased tissue perfusion, which causes obtundation, coma, and death. Patients with chronic symptomatic pericardial effusions will often exhibit tachycardia, jugular venous distension, hepatomegaly, and peripheral edema.  

When examining the patient, one should listen for early signs of cardiac tamponade: (1) muffled heart sounds and perhaps a positional pericardial friction rub, and weak apical pulse; (2) presence of a compensatory tachycardia; (3) abdominal venous congestion and possible peripheral edema; and (4) a fever. The signs and symptoms of pericardial effusion and cardiac tamponade may be mistaken for those of other pulmonary complications or pleural effusions. Many cancer patients have both pleural and pericardial effusions. Unfortunately, symptoms of cardiac tamponade may be the first indication of the presence of pericardial effusion. 

The triad of hypotension, increased jugular venous pressure, and quiet heart sounds that are diagnostic for pericardial effusion occurs in less than a third of patients. If clear lung fields are present, this can help the clinician differentiate between pericardial effusion and congestive heart failure. Pulsus paradoxus is a cardinal sign of cardiac tamponade. It occurs in 77% of those with acute tamponade and in only about 30% of those with chronic pericardial effusion. However, its absence does not rule out pericardial effusion. Pulsus paradoxus is a fall in systolic blood pressure of greater than 10 mmHg with inspiration. Normally, blood pressure lowers on inspiration, but when the heart is compressed it receives even less blood flow. The resulting lowered volume and output result in a greater decrease in blood pressure. Hepatogjugular reflux is a late sign of cardiac tamponade. 

Late in the process of deterioration, diaphoresis and cyanosis are also present. The patient develops increasing ascites, hepatomegaly, peripheral edema, and central venous pressure. Decreased renal flow progresses to anuria. Further impairment in tissue perfusion leads to loss of consciousness, obtundation, coma, and death.

Diagnostic Procedures

Initially, a standard chest x-ray is likely to show a change in the size or contour of the heart and clear lung fields. A pleural effusion may be evident in up to 70% of patients. Chest x-ray can also demonstrate mediastinal widening or hilar adenopathy. This diagnostic tool is cost-effective, minimally invasive, readily available, and may detect tamponade before the patient becomes symptomatic. However, when used alone, it is not specific enough to diagnose pericardial effusions and does not indicate the level of heart decompensation.

2-D echocardiogram (2-D echo) is the most sensitive and precise test to determine if pericardial effusion or cardiac tamponade is present. It can be used at the bedside and is noninvasive. Some cancer patients may have both pericardial effusions and pleural effusions. Pleural effusions can mimic the signs and symptoms of pericardial tamponade, causing symptoms of dyspnea and respiratory distress. Chest x-ray may hide or mimic the presence of pericardial tamponade, so depending on the goals of care, a 2D-echo should be performed to differentiate between these phenomena and to detect decompensation of the heart.

Other tests, including MRI and CT, can be used to detect effusions, pericardial masses and thickening, and cardiac tamponade. However, these tests do not indicate how well the heart is functioning, and they have limited use due to safety and comfort concerns in very ill patients. If echocardiography is not available, a cardiac catheterization, which will detect depressed cardiac output and pressure levels in all four chambers of the heart, may be considered on a case-by-case basis.

Medical and Nursing Management

Options for medical management include pericardiocentesis with or without catheter drainage, pericardial sclerosis, percutaneous balloon pericardiomyotomy, pericardiectomy, pericardoperitoneal shunt, tunneled pericardial catheters, and radiation therapy and chemotherapy, and aggressive symptom management without invasive procedures.

Pericardiocentesis

The most simple, safe, and effective (97%) treatment is echocardiography-guided pericardiocentesis, with a procedural morbidity of 2% to 4% and mortality of 0%. Since more than 50% of pericardial effusions reoccur, it is recommended that a 60-cm pigtail catheter (6 to 8 French) be threaded over the needle to allow for drainage of fluid over time. The procedure can be performed emergently at the bedside, blindly, or with ECG guidance, but it should not be attempted in this manner except in extreme emergencies. Adverse complications of the blind procedure include myocardial laceration, myocardial “stunning,” arrhythmias, pneumothorax, abscess, and infection. The failure rate of this procedure is 10% to 20% because of posterior pericardial loculation or catheter obstruction.

Pericardial Sclerosis

Patients who experience pericardial tamponade face a 50% rate of recurrence when the underlying disease is not effectively treatable. Pericardial sclerosis should be considered in those patients whose disease is not being actively or effectively treated. Pericardial sclerosis is defined as the instilling of chemicals through an indwelling catheter into the pericardial sac for the purpose of causing inflammation and fibrosis, to prevent further fluid reaccumulation. Doxycycline and
bleomycin are the most common drugs instilled into the pericardial space.\textsuperscript{126} A common side effect of sclerosing therapy is severe retrosternal chest pain, especially with talc administration, and sometimes with bleomycin therapy.\textsuperscript{126} A preemptive pain management plan is essential for the well-being of the patient. Arrhythmias, catheter occlusion, and transient fever of up to 38°C without associated bacteremia are also associated complications, primarily of talc and bleomycin therapy.\textsuperscript{114,135,136} While sclerosing therapy may initially be "successful," that is, evidence of disappearance of effusion or absence of tamponade symptoms for more than 30 days, multiple instillations may be necessary for true success.\textsuperscript{120} The use of thiotepa has been recommended for pericardial instillation because it can be instilled into the drained space, is not associated with severe pain, and is reasonably effective.\textsuperscript{126} A major complication is pericardial constriction. A serious discussion of risks, benefits, side effects of the therapy, and its impact on quality of life should take place in the context of end-of-life decision-making.

**Percutaneous Balloon Pericardiectomy**

This is a safe, nonsurgical method that can be used to relieve the symptoms of chronic recurrent pericardial effusions.\textsuperscript{120} It is performed in a cardiac catheterization lab under fluoroscopic guidance using IV conscious sedation and local anesthesia. A guidewire is inserted into the pericardial space, and a small pigtail catheter is inserted over the wire. The wire is removed and some pericardial fluid is withdrawn. Next, the pigtail catheter is removed and replaced with a balloon-dilating catheter that is advanced into the pericardial space and inflated. A pericardial drainage catheter is left in place and is removed when there is less than 100 mL of drainage daily.\textsuperscript{120} Patients have reported experiencing severe pain during and after this procedure. A plan for aggressive pain management must be in place before this procedure and rapidly implemented if pain occurs.

Fever and pneumothorax are the most common complications.\textsuperscript{120} Pleural effusion has also been associated with the procedure. It is suggested that percutaneous balloon pericardiectomy can be used in place of surgical drainage in patients with malignancy and a short life expectancy.\textsuperscript{120}

**Surgical Pericardiectomy**

Another option is to surgically create a pericardial "window" (partial pericardiectomy), a small opening in the pericardium and suture it to the lung. This allows pericardial fluid to drain out of the pericardial cavity, especially loculated effusions.\textsuperscript{120} When other procedures fail and the patient is expected to have long-term survival and good quality of life, partial or complete pericardiectomy may be considered.\textsuperscript{120}

**Video-Assisted Thoracoscopic Surgery**

Video-assisted thoracoscopic surgery (VATS), a minimally invasive procedure, can be used to manage chronic pericardial effusions. In this case, a thoracoscope is introduced into the left or right chest and a pericardial window is performed under thoracoscopic vision.\textsuperscript{139,140} The pleura and pericardium can be visualized, tissue diagnosis can be obtained, and loculated effusions can be drained.\textsuperscript{139} It has a 100% long-term success rate, and there is no significant morbidity or mortality associated with its use.\textsuperscript{120}

**Radiation Therapy and Chemotherapy**

In some cases, radiation therapy can be used to treat chronic effusions after the pericardial effusion has been drained,\textsuperscript{120} and when tamponade is not present. It can be effective in radiosensitive tumors such as leukemias and lymphomas, but is less so in solid tumors.\textsuperscript{114} Systemic chemotherapy can be considered if the malignancy is chemotherapy sensitive.\textsuperscript{119} Chronic pericardial effusions and their management can be challenging. Treatment of symptomatic chronic pericardial effusions will depend on patient prognosis, extent of symptoms, presence of concurrent medical conditions, and general condition. In many cases, treatment may be planned and carried out in a less urgent manner, keeping in mind the long-term benefits and side effects of interventions. Optimal treatment should focus on relieving symptoms caused by pressure on adjacent structures and, in the case of underlying malignancy, the first priority should be the promotion of comfort. When choosing a plan, the ability to treat the underlying cause, the long-term prognosis, and patient comfort should be of greatest importance.\textsuperscript{120}

**Nursing Management**

The priority goals in managing this condition are to provide comfort, to promote pain relief, and to reduce anxiety. The nurse should know both early and late signs of cardiac tamponade. Early recognition of these signs and their implications is most important because early intervention may prevent life-threatening sequelae.\textsuperscript{9}

Aggressive symptom management includes the administration of opioids and anxiolytics to reduce pain and anxiety. If invasive cardiac procedures are carried out in an emergency at the bedside, the nurse should be present to provide support to the patient and family, to control pain and anxiety, and to monitor vital signs as indicated.\textsuperscript{9}

**HEMOPTYSIS**

**CASE STUDY 4**

Mr. J, a Patient with Bronchogenic Lung Cancer

Mr. J, a 56-year-old married man, has a long history of cigarette smoking. He recently has been diagnosed with bronchogenic lung cancer. Last week he had one brief episode of
moderate hemoptysis at home that was stopped with laser treatment in the emergency room. He has now been admitted to your unit for uncontrollable cough, dyspnea, and chest pain. His wife of 30 years and their two grown children are at his bedside. The oncologist has just told them that any further treatment will be futile. During your initial nursing assessment, Mr. J tells you, “I’m not afraid of dying. If you can just keep me comfortable and help my family, I’ll be happy.” The family agrees with his desire not to be resuscitated, and plans are being made for him to return home under hospice care. His wife asks you, “The oncologist told me that there might be more bleeding from his lungs. What do we need to be prepared for at home?”

---

**Key Points**

- Hemoptysis occurs commonly in patients with advanced cancer and is most commonly due to malignant infiltration or infection.
- Hemoptysis should be distinguished from gastrointestinal and nasopharyngeal bleeding.
- Hemoptysis frequently provokes considerable anxiety.
- Massive hemoptysis, while rare, is a life-threatening crisis for patient, family, and staff. Massive hemoptysis occurs in fewer than 5% of cases, but the mortality rate is 85% if surgery is not feasible.
- Skilled palliative nursing intervention includes provision of 24-hour psychological support and guidance.

**Definition**

Hemoptysis is defined as blood that is expectorated from the lower respiratory tract. Hemoptysis can be classified according to the amount of blood expectorated: (1) mild—less than 15 to 20 mL in a 24-hour period, (2) moderate—greater than 15 to 20 mL but less than 200 mL in a 24-hour period, and (3) massive—greater than 200 mL to 600 mL in a 24-hour period. The primary risk to the patient is asphyxiation from blood-clot formation obstructing the airway rather than from exsanguination. Massive hemoptysis carries a high mortality rate if not treated.

**Epidemiology**

Tuberculosis is the most common worldwide cause of hemoptysis. The most common causes of hemoptysis in the United States are bronchitis, bronchiectasis, and bronchogenic carcinoma. Other nonmalignant causes of hemoptysis are lung abscess, sarcoidosis, mycobacterium invasion, emphysema, fungal diseases, and AIDS. There is no underlying cause found in 15% to 30% of hemoptotic episodes.

Metastatic lung disease caused by other primary tumors is associated with nonfatal hemoptysis. Tumors in the trachea usually cause obstructive symptoms rather than massive bleeding. Massive hemoptysis occurs in fewer than 5% of cases, but the mortality rate is 85% if surgery is not feasible. Bleeding occurs most often from proximal endobronchial tumors that are not amenable to surgical intervention. Prognosis is usually grim in the case of end-stage lung disease and in the setting of massive hemoptysis.

**Pathophysiology**

Each lung is supplied with blood by way of two circulatory systems. Pulmonary circulation delivers blood under low pressure from the right ventricle to the alveolar capillaries, where oxygen and carbon dioxide are exchanged. Bronchial circulation arises from the systemic circulation that branches off the aorta, which delivers blood to the lungs under high pressure. These systems Anastomose in capillary pulmonary arterioles and pulmonary veins.

The bronchial venous system returns blood to the heart by two pathways: (1) blood is returned to the right atrium by way of the azygous, hemiazygous, or intercostal veins, and (2) blood is returned to the left ventricle by way of the pulmonary veins. The second pathway carries the bulk of bronchial venous return to the heart.

In the setting of inflammation, tumor, or infection, the bronchial vasculature develops new vascularization pathways. Bronchial blood flow increases as the result of increases in both size and number of these collateral vessels. When these vessels are damaged by inflammation, malignancy, or other injury, blood flow is increased and this raises pulmonary vascular pressure. Hemoptysis occurs in the setting of multiple collateral vessels, high vascular pressure, and damaged, enlarged, and diseased airways.

In patients who have HIV disease, bacterial pneumonia and infections cause 63% of episodes of hemoptysis. Kaposi’s sarcoma causes 10% of episodes, and pulmonary embolism causes 4% of episodes. Patients on anticoagulant or thrombolytic therapy may also experience hemoptysis.

**Diagnostic Procedures**

Flexible fiberoptic bronchoscopy is initially the quickest and surest way to visualize the source of bleeding in the upper lung lobes and to localize it in the lower respiratory tract. This procedure can be done at the bedside without putting the patient under general anesthesia, and it can also visualize distal airways. If there is brisk bleeding, the rigid bronchoscope can suction more efficiently, remove clots and foreign bodies, allow for better airway control, and can be used to obtain material for diagnostic purposes. In some cases, bronchoscopy may locate the area of bleeding but not the direct source of bleeding. In this case, the segment of affected tissue may be purposely suctioned until it collapses. Bronchoscopy should not be undertaken if there is evidence of pulmonary embolism, pneumonia, or bronchitis, or when the patient’s condition is so poor or unstable that no further intervention would be undertaken no matter what the results.
If treatment is to be initiated, the combination of bronchoscopy and high-resolution CT can identify the cause of hemoptysis in 81% of patients. It is also quick, noninvasive, and less costly than other modalities. If pulmonary embolism is suspected and therapy is to be initiated, a ventilation-perfusion scan may be warranted.

**Signs and Symptoms**

Respiratory complaints that raise suspicion of bleeding into the lungs may include cough, dyspnea, wheezing, chest pain, sputum expectoration, and systemic clues, such as fever, night sweats, and weight loss. Clues to nasopharyngeal bleeding as the possible source include frequent nosebleeds, throat pain, tongue or mouth lesions, dysphonia, and hoarseness. Clues to GI bleeding as the possible source include the presence of dyspepsia, heartburn, dysphagia. Coffee grounds-colored vomitus and blood in vomitus does not rule out hemoptysis because blood from respiratory sources can be swallowed. Patients and family members should be asked to describe the color of blood, and should be asked about any changes in color and pattern of bleeding in vomitus and stool. During an active bleeding episode, a focused examination should be performed as quickly as possible. If possible, the nasopharynx, larynx, and upper airways should be thoroughly visually examined to rule out an upper airway source of bleeding. If bleeding is brisk and views are obstructed, examination may best be accomplished with bronchoscopy. The patient may be coughing or vomiting blood, and may be short of breath. If possible, sputum, blood and vomitus should be examined. Some patients may not yet have a diagnosis of malignancy. In these cases one should note clubbing of fingernails and presence of cervical or supraclavicular adenopathy. This may indicate the presence of a malignancy. Massive bleeding may take place in the lung without the presence of hemoptysis, so listening to lung sounds is very important. Auscultation of the lungs may reveal localized wheezing, an indication of possible airway obstruction. Fine diffuse rales and asymmetric chest excursion may indicate the presence of an infectious or consolidative process. If petechiae and ecchymosis are present, then there should be strong suspicion that a bleeding diathesis is present.

**Medical and Nursing Management**

If the episode of bleeding is severe and the goal is active treatment or prolongation of life, then the primary focus is to maintain an adequate airway. This will usually require endotracheal intubation, which may have to be performed immediately at the bedside, and oxygenation. If bleeding can be localized and controlled quickly, a short period of intubation may be considered if it will allow for improved quality of life. Specific methods of treatment include radiation therapy, laser coagulation therapy, bronchial arterial embolization, endobronchial balloon tamponade, epinephrine injection, and iced saline lavage, and, in very rare cases, surgical resection.

**Radiation Therapy**

External-beam radiation therapy can stop hemoptysis in more than 80% of cases, especially in those patients who have unresectable lung cancers. The goal is to provide therapy in the shortest time period possible, at the lowest dose to achieve symptom control while minimizing side effects. Complications of therapy are radiation fibrosis, and, unfortunately, massive hemoptysis.

Endobronchial brachytherapy has been effective in some patients who have failed previous external-beam radiation attempts. Brachytherapy and bronchoscopy laser therapy have also resulted in resolution of hemoptysis. Results have not been as favorable in patients who have failed previous external-beam radiation therapy or when combined with laser therapy. Side effects associated with brachytherapy, particularly high-dose brachytherapy, include mucositis, fistula formation, and fatal hemoptysis. The benefits of this treatment should be carefully weighed against potential side effects and their impact on quality of life, particularly in those patients who have short-term prognoses.

**Endobronchial Tamponade**

In this procedure, flexible bronchoscopy is used to find the bleeding site after the site has been lavaged with iced saline. A balloon catheter attached to the tip of the bronchoscope is placed on the site and is then inflated and left on the bleeding site for 24 to 48 hours. In the case of life-threatening hemoptysis, a rigid bronchoscope should be used. This is not a uniformly successful procedure, and should be considered a temporizing measure.

**Laser Coagulation Therapy**

In the case of obstructing tracheal tumors, Nd-YAG photocoagulation may control bleeding from endobronchial lesions, and it has a response rate of 60%. Anecdotal reports of the effectiveness of electrocautery to control hemoptysis have been reported; argon plasma coagulation has led to resolution of hemoptysis for at least a 3-month followup. However, highly vascular tumors are at risk for bleeding when exposed to laser therapy.

**Bronchial Arterial Embolization**

When an endoscopically visualized lung cancer is the source of bleeding, bronchial artery embolization is effective as a palliative intervention. It stops bleeding in 77% to 93% of cases. Bronchial artery embolization, preceded by bronchoscopy, involves injecting a variety of agents angiographically into the bronchial artery to stop blood flow. Thirty percent of
patients will rebleed within the first or later months, and repeated embolizations may be required.\textsuperscript{158,169}

There are major risks of this procedure, including transverse myelitis, paraplegia, ischemic colitis, severe pneumonia, esophagobronchial fistula formation, and temporary severe retrosternal pain.\textsuperscript{170} Superselective catheterization now reduces the chance of inadvertently catheterizing the spinal cord branch of the bronchial artery, which has led to spinal cord paraplegia in the past.\textsuperscript{171} The risks of rebleeding and the prospect of having repeated embolizations should be carefully reviewed and discussed with the patient and family before carrying out this therapy.

**Endobronchial Epinephrine Injections**

A 1:10,000 epinephrine solution may be instilled on visualized lesions to constrict veins and reduce bleeding. Vasopressin and chlorpromazine have also been used in this procedure, which is performed in patients who are not candidates for surgery and when bronchial artery embolization is not available.\textsuperscript{143,154}

**Iced Saline Lavage**

Iced saline solution lavage has been used as a temporary non-standard measure to provide improved visualization and localization of the bleeding site. It does not appear to improve outcomes.\textsuperscript{143,154}

**Surgery**

In rare cases, some patients who continue to have life-threatening hemorrhage after receiving other therapies may be considered as candidates for surgical intervention. Only those whose life expectancy, condition, ability to tolerate major surgery, and ability to maintain an airway make them suitable candidates, should be considered. It is important to remember that most lung cancers are well advanced at diagnosis and that undertaking this procedure may not meet quality-of-life goals for those with short-term prognoses.\textsuperscript{143}

**Palliative Care**

When a decision has been made to forgo aggressive treatment measures, then promotion of comfort for the patient is the primary goal. Death from massive hemoptysis is usually rapid, occurring within minutes. However, even when the family has been carefully "prepared" for this possibility and coached in a step-by-step manner in what to do, family members inevitably remain unprepared and distraught if a massive hemorrhage does occur, especially in the home, without medical personnel around. Preemptive planning includes anxiolytic and opioids readily available in the home, a 24-hour palliative care number to call for immediate guidance and support, and dark-colored towels to make the viability of blood less overwhelming.

---

**SPINAL CORD COMPRESSION**

**CASE STUDY 5**

**Mr. L, a Patient with Prostate Cancer**

Mr. L, a 79-year-old widowed ex-postal worker, has been treated with hormone therapy for his prostate cancer for the past 2 years. You’ve seen him once since he was discharged from the hospital 6 months ago. “I told them I didn’t want any of that chemotherapy stuff, and I didn’t want to go under the knife either.” He lives with his 44-year-old divorced daughter, who works two jobs and is home only at night. Mr. L has done well until the last few weeks, when he began to complain of increasing low-back pain, especially at night. He’s been taking Tylox for the pain and says “it helps some.” You receive a call from Mr. L, who tells you “I took a bit of a fall last night, but I’m OK now. Could you come out and check me over?” When you arrive at his house, you notice that Mr. L has a bruise under his right eye but no other visible injuries. He tells you “I just got weak and slid to the floor. I feel fine now.” On further questioning, you learn that his back pain has markedly increased in severity at night, although it decreases when he stands. In addition, Mr. L complains of more difficulty in moving his bowels and some difficulty in urinating. He attributes the pain to “just an old disk problem I had some years back.” He finally admits that he’s been having more difficulty walking lately, but doesn’t want to worry his daughter—“She’s got enough on her mind as it is.” Before you can make any recommendations, Mr. L says, “I don’t want to go back to the hospital for any tests. I don’t want them to do anything else to me.”

**Key Points**

- Pain is the primary presenting symptom of spinal cord compression. It may be present long before neurological dysfunction occurs.
- The pain is classically worse when lying flat and improved when upright.
- In a patient with cancer, increasing back pain that is worse when lying flat and improved when standing is presumed to be cord compression until proven otherwise.
- Early detection and treatment may prevent permanent loss of function. It is therefore considered a medical emergency.
- The use of steroids and radiation therapy in patients with far advanced cancer can decrease the pain and usually preserve function. Steroids alone can usually decrease pain and preserve function in those who are close to death and do not want to undergo radiation therapy, even in truncated form.

**Definition**

Spinal cord compression (SCC) is compression of the thecal sac at the level of the spinal cord or cauda equina. Spinal cord injury may cause progressive and irreversible neurological...
damage and requires immediate intervention to prevent disability. SCC in the presence of malignancy often carries a poor prognosis, with a life expectancy of 3 months or less.172

Epidemiology

Compression of the spinal cord and cauda equina is a major cause of morbidity in patients with cancer. It occurs in approximately 5% to 10% of patients with malignant disease,173,174 and is most commonly associated with metastatic disease from tumors of the breast, lung, and prostate. Less than 50% of patients will regain functional losses due to SCC.10,174–176

Compression of the spine in 85% to 90% of cases is caused by direct hematological extension of solid tumor cells into a vertebral body.130,177–180 A less common pathway is by direct extension of tumor from adjacent tissue through the intervertebral foramina. Tumor cells can also enter the epidural space directly by circulating in the cerebral spinal fluid (CSF). Paraneoplastic syndromes, leptomeningeal disease, and toxicity of chemotherapy drugs can cause spinal cord syndromes.181

Nonmalignant causes of SCC include benign tumors, degenerative, inflammatory, and infectious diseases that affect the spinal column, and from trauma, herniated disks, osteoporosis, or other structural diseases.22,181

Pathophysiology

There are 26 vertebrae in the vertebral column: 7 cervical, 12 thoracic, 5 lumbar, 1 sacral, and 1 coccygeal. Inside this flexible protective vertebral column is the spinal cord, which is an elongated mass of nervous tissue covered and protected by membranes called meninges. The outermost layer is the dura mater, the middle layer is the arachnoid membrane, and the innermost layer closest to the spinal cord is the pia mater. The epidural space is located between the outer layer of the dura mater and the vertebral column.10

The spinal cord begins where it is attached to the medulla oblongata in the brain and descends through the foramen magnum of the skull until it ends at the level of the first lumbar vertebra. Lumbar and sacral nerve roots then descend below the distal tip of the vertebral column and spread to the lumbar and sacral areas. These long nerve roots resemble a horse’s tail that is called the cauda equina. Thirty-one pairs of spinal nerves exit from the spinal cord.176,182,183 Transmission of nerve impulses travels the length of the spinal cord to and from the brain in ascending and descending tracts. Impulses from the spinal cord to the brain travel through the anterior spinothalamic tracts, and impulses from the brain to the spinal cord travel through the lateral corticospinal tracts. Injury to these nerves or to the cord itself can result in sensory-motor and autonomic impairment.176

Eighty-five percent of SCCs are extradural in nature.9,10,174,184 That is, they originate outside the cord itself. Extradural metastatic tumors may be osteolytic, where lesions invade the marrow of the vertebrae and cause absorption of bone tissue, which leads to bone destruction. They may also be osteoblastic, where lesions invade the bone marrow and cause bone development, tumor invasion, and collapse of the vertebral body, which then pushes tumor or bone fragments into the spinal cord.10,182,184 Neurological deficits caused by SCC include direct compression on the cord or cauda equina, vascular supply interruption, or pathological fracture, causing vertebral collapse. When nerve tissue dies, neurological regeneration is not always possible. Function may be quickly and irreversibly lost.

Diagnostic Procedures

Plain spinal x-rays are an excellent screening tool and can determine the presence of tumor and the stability of spine.181 They can identify lytic or blastic lesions in up to 85% of vertebral lesions. However, false negatives can occur due to poor visualization, mild pathology, or poor interpretation.177 More than 50% collapse, and pedicle erosion must be present before x-ray can detect SCC.185,186 Epidural spread of tumor through the foramina may not always be visualized using plain x-rays. A bone scan may detect vertebral abnormalities when plain films are negative.187–189

MRI is the imaging choice for emergent SCC.186 It is noninvasive and does not require injection with contrast material. It has an advantage over CT because it can image the entire spine, thus detecting multiple areas of compression.173,181,190 Decisions about diagnostic testing will be tempered by a number of factors, including the potential for treatment, prognosis, patient’s condition, and the family’s wishes for treatment.

Signs and Symptoms

The presence of increasing back pain, worse on lying flat and improved on standing, with or without signs of bowel and bladder impairment, in a patient with a history of cancer, should presumed to be SCC until proven otherwise. Neurological function before initiation of therapy is the single most important prognostic factor in SCC.16 Misdiagnosis of SCC has been attributed to poor history, inadequate examination, and insufficient diagnostic evaluation.191 Patients who have only localized back pain and a normal neurological examination may have more than 75% of the spinal cord compressed. Upper motor neuron weakness may occur above the L1 vertebral body in 75% of patients with SCC at diagnosis. Sensory changes occur in about half of patients at presentation. Sensory change without pain complaint is extremely rare.

A thorough history should pay special attention to the onset of pain, its location, its intensity, duration, quality, and what activities increase or decrease the pain.180,184,182 A history of sensory or motor weakness and autonomic dysfunction should be evaluated and should include onset and degree of weakness; heaviness or stiffness of limbs; difficulty walking; numbness in arms, hands, fingers, toes, and trunk; and change in temperature or touch. Specific questions about bowel, bladder, and sexual function should be asked directly, because patients may not volunteer these symptoms, such as difficulty
in passing urine or stool, incontinence of bowel or bladder, loss of sphincter control, and ability to obtain and maintain an erection. Constipation usually precedes urinary retention or incontinence.184

Physical examination includes observation of the spine, muscles, extremities and skin, and palpation and gentle percussion of vertebrae. Spinal manipulation to elicit pain responses should be carried out cautiously because it may cause muscle spasm or further injury.184 Mental status, cranial nerve, motor function, reflexes, sensation, coordination, strength, and gait should be evaluated (where appropriate to the patient’s status and closeness to death). Focused examination may include performing straight leg raises until the patient feels pain, then dorsiflex the foot. If this action increases pain down the back of the leg, this suggests that nerve root compression is present. Testing of reflexes will indicate the presence and impact of nerve root compression on motor ability. Cord compression may cause hyperactive deep-tendon reflexes while nerve-root compression may cause decreased deep-tendon reflexes. A positive Babinski sign and sustained ankle clonus indicate motor involvement.184

Sensory function should be tested by assessing pain (sharp, dull), temperature (hot, cold), touch (light), vibration (tuning fork test), and position senses (fingers and toes). Examination may reveal a demarcated area of sensory loss and brisk or pressure (tactile) responses should be carried out cautiously because it may cause muscle spasm or further injury.184 Mental status, cranial nerve, motor function, reflexes, sensation, coordination, strength, and gait should be evaluated (where appropriate to the patient’s status and closeness to death). Focused examination may include performing straight leg raises until the patient feels pain, then dorsiflex the foot. If this action increases pain down the back of the leg, this suggests that nerve root compression is present. Testing of reflexes will indicate the presence and impact of nerve root compression on motor ability. Cord compression may cause hyperactive deep-tendon reflexes while nerve-root compression may cause decreased deep-tendon reflexes. A positive Babinski sign and sustained ankle clonus indicate motor involvement.184

Sensory function should be tested by assessing pain (sharp, dull), temperature (hot, cold), touch (light), vibration (tuning fork test), and position senses (fingers and toes). Examination may reveal a demarcated area of sensory loss and brisk or absent reflexes.184 The mapping of positive sensation can be used to pinpoint the level of SCC, usually one or two levels below the site of compression.184 Bladder percussion and digital rectal examination will elicit retention and laxity of sphincter control, a late sign of SCC.

Pain may be reported for weeks to months before any obvious neurological dysfunction.173 Pain may be local initially (in the central back, for example), then progress to a radicular pattern that follows a particular dermatome.173,181 Local pain may be caused by stretching of bone periosteum by tumor or vertebral collapse, and is usually described by the patient as constant, dull, aching, and progressive in nature. Radicular pain is caused by pressure of tumor along the length of the nerve root.10,123,176 The patient who reports radicular pain will describe it as shooting, burning, or shocklike in nature and will state that it is worsened by movement, sneezing, straining, neck flexion, or by lying down. A classic sign of cord compression is if pain is relieved by sitting up or standing and is worsened by lying flat. Also, if pain increases at night when the patient is lying down to sleep, one should be suspicious of SCC rather than degenerative or disk disease.173 Radicular pain is present in 90% of lumbar-sacral SCC, 79% in cervical SCC, and in 55% of thoracic SCC.183 Radicular pain is typically bilateral in thoracic lesions, and is often described as a tight band around the chest or abdomen, but it may also be experienced in only part of one dermatome.173,177 Nonradicular referred pain may also be associated with vague paresthesias and point tenderness.173,177,181 Vigilance is called for when these radicular symptoms occur: (1) shoulder tip pain from C7/T1 metastases; (2) anterior or abdominal, flank, or hip pain from T12-L2 metastases; or (3) lateral or anterior rib pain from thoracic metastases.181

The sequence of neurological symptoms usually progresses in the following manner—first there is pain, then motor weakness that progresses to sensory loss, then motor loss, and finally, autonomic dysfunction.9 The patient will initially complain of heaviness or stiffness in the extremities, loss of coordination, and ataxia.194,195 Sensory complaints include paresthesias and numbness, and loss of heat sensation. Dysfunction begins in the toes and ascends in a stocking-like pattern to the level of the lesion.173 Loss of proprioception, deep pressure and vibration are late signs of sensory loss.10,22,133,176 When the cauda equina is affected, sensory loss is bilateral; the dermatome that follows the perianal area, posterior thigh, and lateral aspect of the leg is involved. Late signs of SCC are motor loss and paralysis. Loss of sphincter control is associated with poor return to functionality.10,22,176

Medical and Nursing Management

The focus of management of SCC should be the relief of pain and preservation or restoration of neurological function. Rapid intervention is required to prevent permanent loss of function and concomitant quality of life. The patient status (e.g., goals of care and closeness to death), rate of neurological impairment, and prior radiation therapy experience are other factors to consider.184 Corticosteroids, surgical decompression, radiation therapy, and adjuvant chemotherapy or hormonal therapy are the standard treatments for SCC.13,184,196

Corticosteroids

Corticosteroids decrease vasogenic edema and inflammation and thus relieve pain and neurological symptoms, and may have some oncolytic effect on tumor.196 Dexamethasone is the preferred corticosteroid because it is less likely to promote systemic edema caused by other steroids or to cause cognitive and behavioral dysfunction, and it improves overall outcomes after specific therapy.173 There has been controversy about dosage and scheduling of dexamethasone therapy in the management of SCC.173,185 There is good evidence to support the use of high-dose therapy because substantially more patients are ambulatory after this treatment. It reverses edema and relieves back pain more rapidly. In animal studies, neurological status has improved more rapidly with high-dose therapy.2,177,178,197–200 High-dose dexamethasone is recommended in ambulatory patients with subclinical SCC.201

Currently, high-dose therapy regimens recommend administering a 100-mg IV bolus of dexamethasone, followed by 24-mg dexamethasone orally QID for 3 days, then tapering the dose over 10 days. High-dose therapy may increase analgesia but can also increase side effects that are significant. These include GI bleeding, hyperglycemia, depression and psychosis, myopathy, osteoporosis, and acute adrenal insufficiency with
A abrupt withdrawal. Low-dose dexamethasone therapy is better tolerated but does not improve the chance of remaining ambulatory. This regimen recommends administering a 10-mg IV bolus of dexamethasone, followed by 4-mg IV QID for 3 days, then tapering the dose over 14 days. Rapid IV push of corticosteroids causes severe burning pain in the perineum, and the patient needs to be warned that this will occur but does not signify that anything is wrong. Corticosteroids are metabolized by the cytochrome P-450 system, and there are implications for interactions with other medications, particularly anticonvulsants.

Decompressive Surgery

The goals of surgery are to decompress neural structures, resect tumor if possible, establish local disease control, achieve spinal stability, restore the ability to ambulate, treat pain, and improve quality of life. Surgery for SCC has been used to (1) establish a diagnosis when tissue is required for histologic analysis; (2) halt rapidly deteriorating function; (3) achieve cure for primary malignancy; (4) treat those with previously irradiated radio-resistant tumor and who have continuing symptomatic progressive loss of function; (5) rule out infection or hematoma; (6) alleviate respiratory paralysis caused by high cervical spinal cord lesions; and (7) decompress and stabilize spine structure. Benefits and burden of surgery to the patient in a palliative care setting must be carefully weighed so that the patient and family can make an informed decision.

Radiation Therapy

Fractionated external-beam radiation therapy (XRT) to the spine is given to inhibit tumor growth, restore and preserve neurological function, treat pain, and improve quality of life. It has been the primary treatment for SCC. Only symptomatic sections of the spine are treated. Seventy percent of patients who are ambulatory at the start of treatment will retain their ability to walk. Thirty-five percent of paraparetic patients will regain their ability to walk, while only 5% of completely paraplegic patients will do so. Primary side effects of radiation therapy include skin alterations of erythema, dry or moist desquamation, pigmentation changes, as well as generalized fatigue.

Nursing Management

The goal of nursing management is to identify patients at high risk for cord compression, to educate the patient and family regarding signs and symptoms to report, to detect early signs of SCC, and to work as a member of the palliative care team in managing symptoms during management of SCC. In those patients who have far advanced disease, palliative care efforts focus on promoting comfort, relieving pain and family support.

HYPERCALCEMIA

Case Study 6

Mrs. H, a Patient with Multiple Myeloma

Mrs. H, a 65-year-old retired LPN, has been receiving outpatient chemotherapy for multiple myeloma. This most recent treatment is under the auspices of an NCI clinical trial, and the patient knows that her cancer is incurable. “I’m a tough ol’ bird. I’ve been around the block a few times, and I know what’s what. They can sugarcoat it all they want. I know this is just buying time, but if it helps somebody else, I’m doin’ it.” Mrs. H lives in a nearby inner-city assisted-living facility. Her children live out of state. She was brought to the hospital when her friends at the facility noticed that she has become more fatigued and lethargic over the past few days, complained of nausea and frequent need to urinate, and seemed a little more confused than usual. You review her lab panels and notice that her ionized calcium is 11.

Key Points

- Hypercalcemia occurs in 8% to 10% of patients with cancer, with an incidence of 40% in patients with breast cancer and multiple myeloma.
- Common presenting signs are fatigue, lethargy, nausea, polyuria, and confusion.
- The combination of nausea and polyuria can lead to dehydration and worsening of hypercalcemia.
- Severity of symptoms depends on the level of free ionized calcium and the speed with which the level rises.
- The serum calcium level is adjusted according to the serum albumin in patients with significant hypoalbuminemia.
- All patients with hypercalcemia who are symptomatic warrant a trial of therapy.
- Control of hypercalcemia will not affect prognosis but may greatly improve symptoms and quality of life in these patients.

Definition

Hypercalcemia is an excessive amount of ionized calcium in the blood. If hypercalcemia is left untreated, the patient may experience irreversible renal damage, coma, or death. Mortality from untreated hypercalcemia approaches 50%.

Epidemiology

About 10% to 20% of cancer patients will develop hypercalcemia at some time during their illness. Carcinomas of the breast and lung, multiple myeloma, and squamous cell carcinomas of the head, neck, and esophagus are the most common malignancies associated with hypercalcemia. Incidence ranges from 30% to 40% for breast cancer with bone
metastases, 20% to 40% for multiple myeloma, 12.5% to 35% for the squamous cell lung carcinomas, and 2.9% to 25% for head and neck malignancies. Hypercalcemia is rare in prostate cancer, GI cancers, and cancers of the biliary tract.

Primary hyperparathyroidism as a cause of hypercalcemia is more common in the ambulatory and asymptomatic population. Other conditions associated with hypercalcemia include lithium therapy, Addison’s disease, Paget’s disease, granulomatous disease, vitamin D intoxication, hyperthyroidism, vitamin A intoxication, and aluminum intoxication.

**Pathophysiology**

Calcium helps the body to maintain its acid-base balance, maintain permeability of cell membranes, promote coagulation, and maintain proper nerve and muscle function. Under normal circumstances, bone resorption and bone formation are in a steady state and are regulated by three hormones—parathyroid hormone (PTH), calcitriol (1,25 dihydroxyvitamin D, a metabolite of vitamin D), and calcitonin. These hormones act at bone sites, in the intestine, and in the kidney. PTH directly increases resorption of calcium from the bone and calcium resorption in the renal tubule. Calcitriol stimulates absorption of calcium in the intestine. It enhances bone resorption and increases renal resorption. Calcitonin is excreted by the thyroid gland and inhibits bone resorption and increases excretion of calcium.

Bone undergoes constant remodeling in the human body. Osteoblasts form bone and osteoclasts resorb bone. About 99% of the body’s calcium is found in bone. The remaining 1% circulates in the blood or is found inside cells. Half of plasma calcium is bound to either protein (albumin) or to other ions, such as phosphate, carbonate, or citrate. The remaining calcium circulates as free ions. Since free calcium is biologically active, its level is maintained in a narrow range in the normally physiological state.

Hypercalcemia in malignant disease is primarily due to increased mobilization of calcium from bone. Increased renal tubular calcium resorption is also a factor in hypercalcemia of malignancy. There are three major mechanisms that contribute to the development of malignant hypercalcemia. First, higher levels of PTHrP (parathyroid hormone-related protein) are found in hypercalcemic patients who have solid tumors, particularly squamous cell carcinomas. The presence of elevated PTHrP levels is associated with more advanced cancer, a worse prognosis, and a poor response to bisphosphonate therapy. Approximately 80% of cases of malignant hypercalcemia are related to the presence of this protein.

Second, osteolysis of bone is caused by the release of tumor and other cell mediators. When this mechanism is operating, hypercalcemia occurs late in disease and is usually associated with extensive osteolytic bone metastases. Third, the increased production of calcitriol by lymphoma tumor cells, for example, leads to increased resorption of calcium in the gut. Hypercalcemia induced by calcitriol usually responds to corticosteroid therapy.

The kidney normally adapts to disturbances in calcium homeostasis. However, in the presence of malignancy, patients may experience treatment or disease-related side effects including vomiting, mucositis, anorexia, dysphagia, and fever, all of which can lead to volume depletion. This imbalance signals the kidney to reabsorb sodium to correct extracellular volume depletion. Calcium and sodium resorption are closely linked in the body; when sodium is resorbed, calcium is also resorbed. As calcium ions are resorbed in the kidney, the tubules lose their ability to concentrate urine, leading to high-output polyuria and further dehydration. Poor renal perfusion, reduced glomerular filtration and compromised excretion of calcium lead to a further increase of calcium in the blood. Ultimately, renal failure will occur.

A high calcium level can alter the patient’s mental status significantly, which, in turn, can greatly affect the patient’s ability to drink fluids. Cellular dehydration and resulting hypotension are exacerbated by decreased proximal renal tubule reabsorption of sodium, magnesium, and potassium. Bone loss due to immobilization, lack of physical exercise, inappropriate use of thiazide diuretics, poor diet, and general physiological wasting will also increase the amount of free calcium ions in the circulation, further increasing calcium levels.

**Diagnostic Tests and Procedures**

The ionized calcium concentration is the most important laboratory test to use in the diagnostic workup for hypercalcemia. It is the most accurate indicator of the level of calcium in the blood. (There is only a fair correlation between the total serum calcium level and ionized calcium.) When ionized calcium cannot be used as a diagnostic tool, the total serum calcium value may be used, but it must be corrected for serum albumin. A rule of thumb is to add 0.8 for each 1 g/dL the albumin has dropped below the normal range (3.7 to 5 g/dL).

**Signs and Symptoms**

Symptoms of hypercalcemia, their severity, and how quickly they appear will vary from patient to patient. The extent of metastatic bone disease is not associated with hypercalcemia levels. It is important to remember that patients, especially the elderly and the debilitated, may experience severe symptoms when serum calcium is not extremely elevated. Symptoms of hypercalcemia, such as vomiting, nausea, anorexia, weakness, constipation, and impaired mental status, may be mistakenly attributed to the disease or effects of treatment. Factors that will influence patients’ response to hypercalcemia include age, performance status, renal or hepatic failure, and sites of metastatic disease.

Patients with a corrected serum calcium level less than 12 mg/dL who are asymptomatic can be considered to have mild hypercalcemia. Patients who have a serum calcium level between 12 and 14 mg/dL should be closely monitored and may require urgent intervention, depending on goals of care in the palliative setting. Those patients with a calcium level greater than 14 mg/dL, which
Bisphosphonate Therapy

Most hypercalcemic patients are treated with bisphosphonate therapy. It is an effective therapy for a number of cancers. Bisphosphonate therapy inhibits bone resorption by osteoclasts, thus reducing the amount of calcium released into the bloodstream. Several IV bisphosphonates and amino-bisphosphonates are available for use in patients. Pamidronate and etidronate are available in the United States. Newer agents include risedronate sodium, ibandronate, and zoledronic acid.

Pamidronate has been the most frequently used bisphosphonate. It is more potent and produces a longer response that often begins within 24 hours of IV administration and lasts for 15 days. Pamidronate appears to be safe in the usual dose of 60 mg to 90 mg IV given approximately every 3 to 4 weeks. In general, there is a 60% response to a 60-mg dose and a 100% response to a 90-mg dose.

Since hypercalcemia tends to recur, pamidronate must be given approximately every 2 to 3 weeks. Side effects of pamidronate therapy include low-grade fever appearing within 48 hours of treatment, redness, induration, and swelling at the site of catheter. Hypomagnesia and hypocalcemia may also occur. Rapid administration of IV bisphosphonates can cause significant pain and this practice should be avoided. Subcutaneous administration of clodronate has been found to be an efficient treatment for malignant hypercalcemia. This route may be particularly useful in hospital, home, and hospice settings and spares the patient discomfort and the costs associated with transportation and IV administration in the hospital environment.

Calcitonin

Calcitonin inhibits resorption of calcium and can rapidly restore normocalcemia, often within 2 to 4 hours of administration. It is much less effective than pamidronate. Its role in managing hypercalcemia is limited to short-term use, usually of only 2 to 3 days’ duration. Side effects are usually mild and include nausea and vomiting, skin rashes, and flushing.

Gallium Nitrate and Plicamycin

Gallium nitrate is an effective bone resorptive agent. Its mechanism of action is unknown. Its main disadvantages are that it has potential to cause nephrotoxicity, and it must be given as a continuous IV infusion over 5 days. Plicamycin is an anti-tumor antibiotic. Its mechanism is unknown. It has a hypocalcemic effect that occurs within 48 hours of administration and that lasts for 3 to 7 days, but it exhibits marrow, hepatic, and renal toxicities. Individual response variations make this drug unpredictable, and it must be administered repeated.

Corticosteroids

Corticosteroids have a limited role in the treatment of hypercalcemia.

Dialysis

The use of dialysis has been reserved for those patients who have severe hypercalcemia, renal failure, congestive heart
failure, and cannot be given saline hydration.232,233 The decision to offer this therapy is made on a case-by-case basis, but, in general, dialysis is not offered in the palliative care arena.

**Palliative Nursing Care**

Hypercalcemia can cause significantly painful and distressing symptoms, including bone pain, agitation and confusion, severe constipation, and delirium. Treatment of hypercalcemia can reduce pain and other symptoms, improve quality of life, and reduce hospitalizations. At end of life, the promotion of comfort and management of symptoms are the primary goals of the palliative nursing care. If hypercalcemia cannot be reversed or the patient decides that the burden of interventions is greater than the benefit, the patient should be given the option of discontinuing such treatment. Ongoing management of symptoms, including sedation if desired, must be guaranteed to the patient and their family.

**CONCLUSION**

This chapter addressed a group of syndromes, which, unless recognized and treated promptly, will cause unnecessary suffering for the patient and family. Emphasis has been given to the epidemiology and basic pathophysiology of each syndrome as well as diagnostic assessment. Providing this information, although by necessity limited in detail, enables the palliative care nurse to explain to the patient and/or family why particular symptoms are occurring and why a particular management approach is being suggested. Treatment advice and decisions are always couched within the framework of “Is the underlying cause reversible or not?”, “What is the benefit/burden ratio of the treatment and how does that fit in with the patient’s values and goals?”, “What is the likely outcome if the syndrome is not treated?”, “How will resultant symptoms be managed?”, “Is palliative sedation available to a patient at end of life if desired?”, and “Will the site of care impact on treatment decisions?”

Symptom Assessment and Management

Symptom Assessment and Management

This page intentionally left blank
**Key Points**

- Palliative sedation is sedation used to control refractory and unendurable symptoms at the end of life when control of these symptoms is not possible with less aggressive measures.
- Determining refractoriness of symptoms and prognosis of hours to days to live is difficult and requires assessment and management by skilled practitioners with advanced palliative training.
- Patient/family/proxy involvement is critical in decision-making concerning use of palliative sedation or terminal weaning. Clear communication with significant others, clear documentation of the meeting, and informed consent are necessary.
- Withholding or withdrawing life support has increased dramatically, from 51% of all intensive care unit (ICU) deaths in 1987 to 90% in 1993.
- Nursing professionals in the acute units and the ICU should train new nurses in the skills required to withdraw and withhold treatment. These skills do not come easily; a concerted effort should be made to provide proper training to ensure patients a painless, dignified, peaceful death.
- The principle of double effect holds that an act with more than one potential effect (at least one good and one bad) is ethical if certain conditions are met. For example, medications administered in the process of terminal weaning from a ventilator or palliative sedation for refractory dyspnea are intended to provide comfort rather than hasten death.

In the United States, approximately 2.5 million people die each year, with >60% of those deaths occurring in hospitals. These statistics are alarming and support the public’s concern for the dying. The results of a survey by the Last Acts Coalition, funded by the Robert Wood Johnson Foundation, suggested that the public feels that deaths in hospital settings are not well managed; 93% of respondents stated that it was “very important” or “somewhat important” to improve how the health care system cares for dying Americans. This survey also stated that patients and their family members clearly want to be involved in decision-making (42%) and to be comfortable at the end of life, with well-managed symptoms (39%) and with care that does not exhaust their life savings (73%).

Palliative care providers are faced with the challenge of managing a multitude of complex symptoms in terminally ill patients. Although many of these symptoms respond to skilled palliative management, others may remain refractory to treatment. Suffering at the end of life involves physical, psychological, social, and spiritual distress. In most situations, multidisciplinary palliative interventions provide effective comfort. However, in some instances, suffering becomes refractory and unbearable. Information about end-of-life decision-making is scarce and usually is obtained after the death by retrospective research methods. Therefore, decisions about starting or forgoing potentially life-prolonging or life-shortening therapy are not well understood.

Research and experience suggest that much work must be done in palliative care in the areas of sedation and advanced therapy decision-making, both before and at the end of life. This chapter explores the use of palliative sedation and terminal weaning in the hospital setting. Specifically, it presents case studies involving palliative sedation and withholding or withdrawing life support, definitions of palliative sedation, incidence of sedation use, reasons for sedation, sedative medications, treatment locations, guidelines for use of sedation, nursing care, ethical issues, informed consent, time to death, and the role of the nurse caregiver.
The following cases provide examples of clinical situations in which decision-making regarding sedation and terminal weaning was required.

**CASE STUDY I**

**Mr. M, a 35-Year-Old Man with Metastatic Lung Cancer**

Mr. M, a 35-year-old Asian patient with widely metastatic lung cancer, was transferred to the acute palliative inpatient unit for management of severe delirium. His mother and his life partner, a nurse, accompanied the patient to the unit. He was also under psychiatric care for bipolar disorder and was taking six psychotropic medications. Although Mr. M. had uncontrolled large muscle movements, he was arousable and could follow simple commands. Both his mother and his significant other were very distressed. This is a fairly typical patient presentation to an acute palliative unit. Approximately 25% to 35% of this type of delirium is reversible.10

**CASE STUDY II**

**Mr. Z, a 52-Year-Old Man with Mesothelioma**

Mr. Z, a 52-year-old man was admitted to the intensive care unit (ICU) status post left pneumonectomy with mesothelioma in his remaining lung. He had been married for 30 years and had two adult children: a 23-year-old daughter and 26-year-old son. He was awake and alert but ventilator dependent, with a tracheostomy, and in renal failure. Renal dialysis was being discussed by the physicians. The patient was surrounded by his wife, daughter, and family friends. When the patient was informed that his lung cancer was metastatic, he expressed his desire to go home and discontinue mechanical ventilation. The patient’s request to discontinue mechanical ventilation was unrealistic but began the dialogue for terminal weaning.

**Definitions**

There is no standardized or consistent search term for palliative sedation across databases. The phrase “terminal sedation” was first used by Enck,11 who employed the term after a review of patient cases in which physical symptoms were treated with sedation at the end of life. Since that time, numerous efforts have been made to define terminal sedation clearly and to separate it from sedation used in other medical settings.4–7,12–14 Terminology for palliative sedation varies and includes palliative sedation,4,6,7,13 terminal sedation,4 total sedation,15 sedation for intractable symptoms,16 and sedation for distress in the imminently dying.4 Palliative sedation has also been termed “slow euthanasia,”17 but terms such as this should not be used, because the intent of palliative sedation should be comfort rather than hastening death. Currently, most authors have elected to use the term “palliative sedation.”6,7

At the authors’ institution, the term “palliative sedation” is used. It is defined as the monitored use of medications (midazolam or propofol) that induce sedation to control refractory and unendurable symptoms near the end of life when control of these symptoms is not possible with less aggressive measures. The purpose is to control symptoms, not to hasten death. The acceptance of the term “palliative sedation” over “terminal sedation” has evolved to emphasize the difference between management of refractory symptoms and euthanasia. Table 24–1

<tr>
<td><strong>Imminent death:</strong> death that is expected to occur within hours to days based on the person’s condition, disease progression, and symptom constellation.</td>
</tr>
<tr>
<td><strong>Intent:</strong> the purpose or state of mind at the time of an action. Intent of the patient/proxy and health care provider is a critical issue in ethical decision-making regarding palliative sedation. Relief of suffering, not hastening or causing death, is the intent of palliative sedation.</td>
</tr>
<tr>
<td><strong>Palliative sedation:</strong> the monitored use of medications intended to provide relief of refractory symptoms by inducing varying degrees of unconsciousness, but not death, in terminally ill patients (Hospice and Palliative Nurses Association [2003], reference 55).</td>
</tr>
<tr>
<td><strong>Double effect:</strong> in terminal sedation, an act with more than one potential effect (one good and one bad) is ethical if (1) the intended end (relief of distressing symptoms) is a good one, (2) the bad effect (death) is foreseen but not intended, (3) the bad effect is not the means of bringing about the good effect (death is not what relieves the distress), and (4) the good effect outweighs the bad effect (in a dying patient, the risk of hastening death for the benefit of comfort is appropriate) (Thorns [2002], reference 84).</td>
</tr>
<tr>
<td><strong>Refractory symptom:</strong> a symptom that cannot be adequately controlled in a tolerable time frame despite the aggressive use of usual therapies and that seems unlikely to be adequately controlled by further invasive or noninvasive therapies without excessive or intolerable acute or chronic side effects.</td>
</tr>
<tr>
<td><strong>Terminal weaning (slow withdrawal):</strong> removal of mechanical ventilation, which is performed by gradually reducing the fraction of inspired oxygen (Fio₂) and/or mandatory ventilator rate, leading to the development of hypoxemia and hypercarbia, when the patient is not expected to survive.18,20</td>
</tr>
<tr>
<td><strong>Terminal extubation (abrupt withdrawal):</strong> removal of an endotracheal tube.19</td>
</tr>
</tbody>
</table>
lists common terms used in relation to palliative sedation and terminal weaning.

The term “terminal wean” is used when mechanical ventilation is withdrawn and the patient is not expected to survive. In 1983, Grenvik was the first to describe a systematic approach to ventilator withdrawal, suggesting a gradual reduction in the ventilator setting over several hours. Many strong opinions exist regarding slow withdrawal versus abrupt withdrawal. A commonly used expression is “terminal extubation,” which is removal of the endotracheal tube. This technique usually occurs after administration of boluses of sedatives or analgesics, or both. Another term used to describe this technique is “terminal wean,” which is performed by gradually reducing the fraction of inspired oxygen ($F_{\text{IO}}$) and/or mandatory ventilator rate, which may lead to the development of hypoxemia or hypercarbia or both. The decision to remove the endotracheal tube during or after a terminal weaning process is practitioner dependent at this time. Perhaps best practices could be decided by further research.

### Reasons for Sedation

Although sedation has been used to control noxious symptoms and for surgical anesthesia, its use at the end of life has not been so generally accepted. Common symptoms at the end of life include pain, dyspnea, delirium, and nausea and vomiting, as well as hopelessness, remorse, anxiety, and loss of meaning for the patient. Palliative sedation is most commonly used for physical symptoms that are not responding to aggressive symptom management and are causing life to become unbearable. Table 24–2 outlines common symptoms for which palliative sedation is used. Fainsinger and associates, in a multicenter international study, found that 1% to 4% of terminally ill patients needed sedation for pain, 6% to 6% for nausea and vomiting, 0% to 13% for dyspnea, and 9% to 23% for delirium. In a review of 27 reports, 342 patients had more than one symptom. Chater’s survey of palliative care experts found that more than half of patients had more than one symptom and that 34% received sedation for nonphysical symptoms such as anguish, fear, panic, anxiety, terror, and emotional, spiritual or psychological distress.

The concept of refractoriness of nonphysical symptoms or existential suffering is not as clear. Although there is no clear consensus on palliative sedation for existential suffering, the Oregon experience with physician-assisted suicide indicates that patients want assisted suicide to avoid dependence on others and to control the timing and manner of their death. Psychological suffering is a more nebulous symptom for sedation, but it can be just as distressful and refractory as physical

suffering.\textsuperscript{34,35} Table 24–3 identifies interventions that should be made before defining a physical symptom as refractory.

In the ICU setting, reasons for terminal sedation are related to both refractory symptom management and terminal weaning from a ventilator. The decision for terminal weaning may occur if the patient’s condition is terminal, attempts to wean from the ventilator have failed, and the family or patient concurs with futility. “Futility” is defined as the perception that the patient has a poor prognosis and is not likely to survive.\textsuperscript{25} Singer and colleagues\textsuperscript{36} described five domains that indicate good end-of-life care: good symptom management, avoiding inappropriate prolongation of the dying process, achieving a sense of control, relieving burden, and strengthening the patient’s relationship with loved ones.

\textbf{Medications}

Drugs used in palliative sedation outside the ICU are benzodiazepines, neuroleptics, barbiturates, and anesthetics.\textsuperscript{6,7,13,16} Midazolam is the most commonly used of these drugs.\textsuperscript{8,37} The drug and route chosen vary based on the route available, location of the patient, and cost, as well as the preference of the provider.\textsuperscript{6} Usually in inpatient settings the medications are given intravenously or subcutaneously and continuously. In palliative sedation, in general, the chosen medication is started at a low dose and titrated upward until the symptom is controlled. Before palliative sedation is started, administration of all previous comfort medications should be continued.\textsuperscript{7} Types and routes are presented in Table 24–4. The type of medication used may be influenced by state regulatory agencies for nursing, medicine, and pharmacy. For example, the Texas Board of Nurse Examiners expresses concern regarding the administration of anesthetics by nurses not certified as nurse anesthetists in nonmonitored settings.

The drugs of choice for refractory symptoms and terminal weaning in the ICU are opiates and benzodiazepines.\textsuperscript{18,20,36,39} These drugs can be continually infused and titrated until the patient appears comfortable. Morphine is a drug of choice because it provides analgesia, sedation, and reduction of dyspnea.\textsuperscript{18} In some instances, barbiturates, haloperidol, and propofol are used.\textsuperscript{40,41} Neuromuscular blocking agents have no therapeutic effect; they should not be started, or should be
stopped if already prescribed, before life-sustaining therapies are withdrawn.38,42 Neuromuscular blockades make it difficult to assess a patient’s comfort level because their use makes movement impossible. Patients may be experiencing pain, respiratory distress, and anxiety but unable to communicate their symptoms.43

If the skilled clinician is available and the patient’s family agrees, the withdrawal of life support can ethically occur in the presence of neuromuscular blockade.42,44 This is useful in cases in which death is expected to be rapid and certain after removal of the ventilator and if the burden to the patient and family of waiting for the neuromuscular blockade to clear the system (up to several days), is inappropriate.

### Treatment Locations

Many hospitals do not have palliative care units. Although the number of fellowship programs for Palliative Medicine in the United States has grown to 20,39 most hospitals and communities do not have access to these specialists. Because palliative sedation should be a last resort for intractable symptoms, expertise in symptom management and end-of-life care to verify refractoriness is needed.6,45 The drugs of choice are classified as anesthesia medications, but institutional polices may limit the choice of agents used. Unfortunately, inappropriate use of benzodiazepines for palliative sedation occurs, and sedation may be implemented by professionals not trained in palliative care.

Unfortunately, palliative sedation seems at cross-purposes with the goals of intensive care. The original intent of admission to an ICU is to aggressively stabilize the patient faced with life-threatening events. The ICU environment allows rapid identification and treatment of life-threatening changes to avoid death.49 Patients and families come to the ICU expecting miracles, and they often are familiar with stories of those who have survived similar experiences, whether real cases or from television. The challenge for health care practitioners in the ICU is to know when to transition from curative to palliative care and then to communicate with the family regarding the patient’s prognosis and decisions about sedation. ### Table 24.5
Palliative Sedation Checklist

#### Part A. Background

- Confirm patient has
  - Irreversible advanced disease.
  - Apparent imminent death within hours, days, or weeks.
  - A “do not attempt resuscitation” order.
- Confirm that symptoms are refractory to other therapies that are acceptable to the patient and have a reasonable/practical potential to achieve comfort goals.
- Consider obtaining a peer consultation to confirm that the patient is near death with refractory symptoms.
- Complete informed consent process for palliative sedation (PS).
- Discontinue interventions not focused on comfort.
  - Discontinue routine laboratory and imaging studies.
  - Review medications, limit to those for comfort, and adjust for ease of administration (timing and route).
  - Discontinue unnecessary cardiopulmonary and vital sign monitoring.
  - Review the role of cardiac support devices (e.g., pacemaker) and disable functioning implanted defibrillators.
  - Integrate a plan to discontinue ventilator support with PS.
- Develop a plan for the use or withdrawal of nutrition and hydration during PS.
- Identify a location and an environment acceptable for providing PS.
- Use providers familiar with PS and the use of sedatives.

#### Part B. Treatment/Care of the Patient

- Institute and maintain aspiration precautions.
- Provide mouth care and eye protection.
- Use oxygen only for comfort, not to maintain a specific blood oxygen saturation.
- Provide medications primarily by IV or SQ route.
- Maintain bowel, bladder, and pressure point care.
- Continue, do not taper, routine opioids.
- Provide sedating medication:
  - Around the clock.
  - Titrate to symptom control not level of consciousness, using frequent re-evaluation.
  - Limit vital sign monitoring to temperature and respiratory rate for dyspnea.
- Choose sedating medication based on provider experience, route available, and patient location.

**Home initial dosing (choose one):**

- Chlorpromazine, 25 mg suppository or 12.5 mg IV infusion every 4–6 h.
- Midazolam, 0.4 mg/h by continuous IV or SQ infusion.
- Lorazepam, 0.5–2.0 mg IV sublingually every 4–6 h.

**Hospital initial dosing (choose one):**

- Chlorpromazine, 12.5–25.0 mg every 4–6 h.
- Midazolam, 0.4 mg/h by continuous IV or SQ infusion.
- Amobarbital or thiopental, 20 mg/h by continuous IV infusion.
- Propofol, 2.5 mg/kg/min by continuous IV infusion.

there is a consensus, the challenge is then to transform the high-tech, fast-paced, often loud ICU setting into a peaceful, serene environment conducive for dying. Even in ideal settings, where palliative care and ICUs coexist, there are still challenges in transferring patients to a less restrictive environment in a safe, timely manner due to the patient’s critical, fragile state. Copies of protocols from the authors’ institution are included in Appendices 24-1 through 24-3 at the end of this chapter.

Guidelines for Use

The use of sedation for refractory symptoms varies. Therefore, the use of clinical pathways or checklists is recommended to ensure optimal and consistent standards of care. Table 24–5 is a sample checklist for palliative sedation. Table 24–6 is a sample checklist used in an ICU setting for terminal weaning. Although evidence is often anecdotal, there has been concern that palliative sedation could be used inappropriately.\(^4\,^6\,^2\,^1\,^4\,^5\) Four factors need to be present for a patient to be considered for sedation. First, the patient should have a terminal diagnosis. Second, the patient should have symptoms that are unbearable and refractory. Consultation with an expert to confirm that the patient is near death with refractory symptoms is recommended. Third, a DNR order must be in effect. Fourth, death must be imminent (within hours to days), although this can be challenging to determine.\(^6\,^7\,^4\,^5\) In the presence of the first three conditions, sedation may be appropriate for a patient with severe distress that has been unresponsive to skilled palliative interventions. Ethics committees or patient advocate services may be useful if there appear to be irresolvable family or staff conflicts. Studies have shown that ethics consultations are useful in resolving conflicts that may otherwise prolong futile and unwanted treatments in the ICU.\(^4\,^7\)

A major function for palliative care is to assist families to make the transition in goals of treatment from cure to comfort. Refractory symptoms and the distress they cause create a very difficult and abrupt need for this transition phase. Use of the interdisciplinary team to both plan for treatment options and participate in family meetings is critical to the success of the team. The social worker plays a vital role in assessing caregiver stress and family dynamics and coordinating family meetings. The chaplain and other psychosocial professionals provide spiritual assistance and counseling in redefining hope and supporting the decision-makers through anticipatory and actual grief.\(^4\,^7\)

Nursing Care: Back to Basics

Communication

An important role of the nurse in the end-of-life process is to facilitate communication and establish trust between the patient, family, and health care providers.\(^4\,^8\) Communication is vital to developing a relationship of trust and avoiding conflict during any illness, but it becomes more important at the end of life. The team has to build a trusting relationship with patients and families as they make difficult decisions. If a patient or family members do not trust the health care team, conflict is likely to result.\(^4\,^8\) Communication includes (1) being honest and truthful, (2) letting patients and families know they will not be abandoned, (3) including them in care decisions, (4) helping the patients and families explore all options, (5) asking clearly what they need from the team, (6) working to ensure that the entire team knows and understands the plan, and (7) most important, active listening.\(^4\,^8\,^5\,^0\)

When the decision is made to use either terminal sedation or terminal weaning, caring and thoughtful communication make a tremendous difference in the family’s experience with the death. The concept of “presence” with the patient and family during the death vigil is difficult to quantify but critical during periods of extreme distress.\(^3\,^1\,^9\) Untreated symptoms cause families and staff to be traumatized by a “horrible death.” For example, 77% to 85% of all cancer patients experience delirium before death.\(^4\,\) Some delirium, 25% to 35%, is reversible,\(^10\) and all patients should be treated for delirium and other distressing symptoms. Loss of inhibition is the hallmark of delirium as global brain function diminishes. Symptoms of moaning, groaning, and restlessness are often interpreted by the family as physical pain. An explanation of the delirium and aggressive treatment is important to comfort the family, who also need support for anxiety, grief, and sadness as they prepare for the death of their loved one. They need continual explanations of and reassurance about what to expect and the opportunity to express their feelings of grief.\(^6\)

Physical Care

Nurses play an essential role at the bedside to administer sedation and monitor symptom response to sedation. It is also important to continually reinforce with the family that the intent of sedation is symptom control and not hastening of death.\(^6\) In collaboration with the physician, evaluation of symptom response and possible need for titration of medication should be done at least every 24 hours once the symptoms are stable.

As the patient becomes more sedated, protective reflexes decrease. The ability to clear secretions decreases, necessitating suctioning and/or medications. Make sure the family understands that the patient can no longer safely swallow. The blink reflex decreases and eyes can become very dry, requiring frequent eye drops (artificial tears). Bowel and bladder management needs to be carefully monitored to maintain comfort. A urinary catheter is often appropriate to minimize the need for frequent changing and cleaning and to prevent skin breakdown. General nursing care for immobilized patients is vital; mattress pads that decrease pressure, excellent skin care, and attention to positioning are all important.\(^5\,^0\,^5\)}

18. Remain at bedside to
   a. assess patient for comfort/discomfort.
   b. promptly administer sedation, analgesics.
   c. provide emotional support to patient and family.
   d. ask patient/family if additional comfort measures are needed.

19. Obtain physician orders for additional or alterations in pain and sedation medications if the end-of-life protocol medications are ineffective in controlling the patient’s discomfort.

20. Respiratory therapist should remain in room until ventilator is functioning at minimal capacity or patient is extubated and the ventilator is removed from the room.

21. Support and educate the patient’s family regarding interpretation of the clinical signs and symptoms the patient may experience during the end of life.

22. Assess the family’s need to be alone with the patient during and after the death process.

23. Assess the family to determine the amount of support they require during the end-of-life process.

24. Assist the family in meeting its needs and the patient’s needs for communication, final expressions of love and concern (e.g., holding a hand, talking with the patient, remembering past events).

25. Discuss signs of death and how the physician will pronounce the patient; the family will be asked to leave the room while the physician examines the patient.

26. If the patient is transferred to the general care floors during end-of-life care, provide the accepting nurse a verbal report and discuss the dosage of IV medications and the signs and symptoms for medication titration. Suggest to the critical care physician or attending physician a patient referral to or consultation with palliative care services.

27. Notify intensive care unit physician to pronounce patient. An ECG strip of a straight line or asystole is not needed to document patient death.

29. Assist family with decisions regarding need for autopsy.

30. Notify clinical nurse specialist Monday through Friday before 3 P.M. to complete death paperwork.

31. Notify in-house administrator after 3 P.M. and on weekends to complete death paperwork.
**Special Considerations in the Intensive Care Unit**

Immediately before terminal weaning, the physician should briefly review the procedure and be available to answer any questions family members may have. Nurses should ask family members whether they have any last-minute questions or concerns. Nurses can reassure the family that comfort is the primary goal and that pain medication is available. If appropriate, nurses should also explain that the patient may need to be asleep to be comfortable. Nurses should also make clear that sometimes the patient may experience involuntary movements but that they do not indicate pain.

Before beginning the weaning process, the nurse should turn off the physiological monitoring alarms and remove any unnecessary tubes or equipment (e.g., restraints, nasogastric tubes). Any unnecessary medications (e.g., vasoactive drips, antibiotics) should be stopped. Before extubation, medications should be administered to establish adequate symptom control as ordered by the physician. Opioids are the most effective agents for relieving the sense of breathlessness, and benzodiazepines are most effective for relieving anxiety. Any additional medications should be readily available. Oxygen should be set at 21% or as ordered by the physician.

The need for additional medications should be continually assessed and readjusted. Once the patient appears to be comfortable, the physician or respiratory therapist removes the endotracheal tube. Throughout this process the nurse should allow space for the patient’s family at the bedside. The decision to stay at the bedside or not is a personal decision and nurses can validate and support whatever decision is made by the family. The family also should be encouraged to assist by wiping the patient’s forehead, holding the patient’s hand, or talking to the patient. The patient and family should be offered chaplaincy or other psychosocial services support throughout the process. After the patient dies, the family should be allowed adequate time to begin the grieving process.

**Time to Death**

One of the concerns many have with palliative sedation is that it might hasten death. Part of this concern stems from the difficulty in predicting the time of death. Several studies using different methodologies have examined effects of sedation on survival rates. The mean time to death in a large four-country study ranged from 1.9 to 3.2 days, and the median time to death in a Taiwanese study was 5 days. A study of patients in Japanese hospices indicated that sedating medications did not shorten the lifespan. However, because of ethical considerations, none of these studies were controlled trials, so it is not possible to determine whether sedation may or may not result in hastening the death. In situations of unbearable distress, sedation remains an appropriate option to relieve suffering.

**Ethical Considerations**

This section describes ethical principles applicable to palliative sedation, which includes “slow euthanasia” and terminal weaning. The ethical and legal principles that apply to palliative sedation are patient autonomy (patient’s choice), beneficence (do good), nonmaleficence (do no harm), futility, and the principle of double effect. This requires informed consent with adequate decision-making capacity. Conflicts can occur if patient, family, and staff beliefs about the goal of therapy are in conflict. Autonomy conflicts with beneficence and nonmaleficence if the roles of the medical and nursing caregivers as healers conflict. The issue of medical futility creates great distress for the physician who is accountable for medical care of a patient or family requesting further treatment that is deemed by the medical team to be futile. Refusal to treat does not mean ignoring patient or family wishes but reflects a concern about doing harm instead of good.
This issue becomes more complicated for nurses at the bedside. Nurses are required to care for the patient based on the physician’s orders with varying ability to express personal beliefs. With skilled palliative management, nurses are included in the entire process. Resolution of dilemmas is difficult but is facilitated by ensuring that the nurse understands the goals and is allowed the option to decline assignment to a patient if uncomfortable with the treatment plan. Nursing leaders across the country are working diligently to create systems that support patients and their families as well as the nurses at the bedside during end-of-life care.

The principle of double effect holds that an act with more than one potential effect is ethical if certain conditions are met. The doctrine of double effect emphasizes four basic conditions: (1) the nature of the act is morally good and is not in a category that is absolutely prohibited or intrinsically wrong; (2) the intent of the act is good, even in the presence of a foreseen bad effect; (3) the means of attaining the good effect (relief of suffering) is not bad; (4) the intended good effects balance or are greater than the bad effects (rule of proportionality). Cowan and Palmer added a fifth condition: that there are no other means to achieve the intended good effect. However, Quill and coworkers argued that clinical justification of palliative sedation is ambiguous, making double effect inappropriate, because palliative sedation causes death and the intentions are not always clear. Cherry suggested that relieving a symptom and proportionality are more appropriate than double effect.

Some authors have suggested that palliative sedation and slow euthanasia are morally equivalent. Billings and Block defined slow euthanasia as the clinical practice of treating a terminally ill patient in a fashion that will assuredly lead to a comfortable death, but not too quickly. Mount argued that Billings and Block’s definition is more a definition of palliative care. Whereas euthanasia is the deliberate termination of life by active intervention of a medical provider for a patient with uncontrolled suffering, palliative sedation is not euthanasia because it is not intended to end life primarily but rather to relieve the distressing symptoms.

The U.S. Supreme Court in 1997 ruled unanimously that “there is no constitutional right to physician-assisted suicide” but “terminal sedation is intended for symptom relief and not assisted suicide . . . and is appropriate in the aggressive practice of palliative care.” The American Nurses Association (ANA) and the Oncology Nursing Society (ONS) have position papers opposed to physician-assisted suicide. Although neither addresses the exact issue of palliative sedation or terminal weaning, both support the risk of hastening death through treatments aimed at alleviating suffering or controlling symptoms as ethically and legally acceptable. The Hospice and Palliative Nurses Association has issued a position paper in support of palliative sedation. Hospitals are being encouraged to develop policies for terminal sedation and against euthanasia and to understand that aggressive and readily available palliative care (including sedation) might actually reduce the demand for euthanasia or assisted suicide. The issue of palliative sedation for existential suffering remains controversial.

In Case Study I, cited earlier, before the transfer to the palliative unit, the primary physician felt uncomfortable with the high level of sedation required for this young and otherwise healthy man to stay sedated. This physician did not object to the patient’s being sedated, but she was concerned with the amount of medication required to appropriately sedate him. The physician initially refused to transfer the patient to the palliative service or to accept the palliative’s team orders for sedation. Although the primary physician never used the term “slow euthanasia,” her actions suggested this concern. The nurses on this medical oncology floor were concerned about “killing the patient with medicine” but also expressed concern that the patient might die of suffocation while awake. The palliative physician requested a medical ethics consultation, but it was not needed because the patient was transferred to the palliative care unit.

The ethical principles that apply to withdrawal of mechanical ventilation are patient autonomy, nonmaleficence, and beneficence. Patient autonomy is the process that allows the patient to make an informed and voluntary decision regarding his or her care. The basis for the ethical dilemma in withholding or withdrawing life support is the balance between patient autonomy and physician autonomy or professional and institutional integrity. A conflict may arise if the patient or family insist that “everything be done” and the health care team believes that continued aggressive support would be inappropriate or futile. In Case Study II, the family could have argued that the patient was not in a condition to make end-of-life decisions and insisted that everything be done or, at the very least, that mechanical ventilation be continued. The patient or family also could have requested further treatment (e.g., chemotherapy, dialysis).

Withdrawal of life-sustaining therapy may be justified if the therapy in question is deemed futile. Medical futility refers to interventions that are unlikely to produce a significant benefit. Practitioners should carefully consider each intervention and whether there would be benefit or harm for the patient. Terminal weaning can be disturbing for those who do not understand the principles that guide caregivers’ actions. The administration of opioids in this setting is justified ethically by the principle of double effect. The double effect principle draws a distinction between the intended effects of a person’s action and the unintended, though anticipated, effects of that action. During the terminal weaning process, the caregiver’s first responsibility is to relieve pain and suffering, whereas the potential for hastening death is tolerated as a necessary evil. The clinician’s primary intent is to relieve the patient’s suffering and not to cause death. The terminal weaning process can be more difficult for the caregiver if the patient is awake and alert enough to participate in the decision to withdraw life support, but the guiding principles remain the same.

In Case Study II, another ethical principle that should be considered is nonmaleficence, or duty not to inflict harm. The patient’s nurse might have viewed the withdrawal of ventilation
and corresponding sedation requirements as inflicting harm. In the case presented, does the patient’s physician have the right to withhold dialysis? Medical futility refers to interventions that are unlikely to produce a significant benefit to the patient. Practitioners should carefully consider each intervention and whether there would be any benefit for the patient. In the case presented, continuing ventilation would only prolong death. There is no reasonable likelihood that the patient could ever have weaned off the ventilator, because his cancer had spread to his remaining lung. Use of life-sustaining or invasive interventions in a patient who is terminally ill may only prolong the dying process. Also, the intervention of dialysis for the patient would only have prolonged the dying process.

Ethical issues are not clearcut. Although respect for patient autonomy is important, it does not mean that health care workers are obligated to provide requested sedation in all circumstances. Principles of intent provide safeguards for palliative sedation and terminal weaning. Closeness to imminent death needs to be assessed, as well as refractoriness of distressing symptoms. With careful application of criteria, palliative sedation cannot be equated with slow euthanasia.

Informed Consent

Palliative sedation is a joint decision and not an arbitrary medical decision. In the palliative care setting, a consent for sedation should be obtained as soon as a symptom is identified as possibly refractory. Sedation can then be quickly arranged if needed. Informed consent regarding palliative sedation or terminal weaning should be more than simply a signature on a form. There is a tendency to discuss the plan of care for the patient at the convenience of the physician and not that of the patient or family. A well planned, compassionate, and clear discussion at the end of life should occur with the family and the patient. The bedside nurse should attend these meetings to provide insight into the care and support needed by the family. It is vital to plan these meetings carefully to ensure that the appropriate family members are present. Allowing the designated decision-maker to invite important people to the planned meeting allows key participants to hear the information at the same time. A religious or spiritual representative may be helpful at these meetings if desired.

Family meetings work well for cohesive and connected family units. In families with more disparity, family members may appear to agree in the group but individually continue to have conflicts about agreed-upon decisions. Nurses and staff need to respond to all questions and be prepared to repeat information and provide support.

The primary physician should begin the family meeting with a brief, clear report on the current condition of the patient. Any supporting documentation of the current condition, such as recent laboratory data or other diagnostic test results, may be helpful in certain cases. Either at the end of the family meeting or the next day in nonemergency cases, an informed consent document needs to be signed by the patient, family, or medical proxy. The family should be provided time to raise all concerns and clarify information.

Next, the treatment options should be discussed. When discussing terminal sedation options, it is important to assess the patient’s and family’s cultural and religious beliefs and concerns. Documentation of the informed consent should include the patient’s name and diagnosis, the parties present, the reason for sedation (symptom distress), and the primary goal (patient comfort), as well as patient terminal status, notation of any professional consultations, documentation that the patient is near death and has refractory symptoms, planned discontinuance of treatments not focused on comfort, plan for hydration and nutrition, and anticipated risks or burdens of sedation. Because it usually is not possible to communicate with the sedated patient, it is important to make sure that the patient and family are ready to proceed with sedation. A well-planned family meeting decreases miscommunication and supports the family during a difficult decision-making time by allowing all pertinent parties to hear the same information at the same time.

In the ICU setting, there should also be a succinct description of the terminal weaning process. One of the most common reasons for withholding or withdrawing life support is the perception that the patient has a poor prognosis. Although there are many published guidelines for withholding and withdrawing life support, the actual implementation of such measures is often difficult for the health care team members as well as the patient and family. Physicians may have a difficult time discussing such interventions with patients and families, and this often leads to the continuation of treatments that are medically inappropriate or futile. The patient and family members should also be allowed sufficient time to reach a consensus about whether to discontinue life support. All members of the multidisciplinary team should understand and be able to discuss the plan of care. The nurse and physician should also carefully document the plan. Because withholding and withdrawing life support and administering palliative sedation can involve health care practitioners other than the attending physician, the health care team should participate in the planning phase. A team approach is vital during this phase of care delivery, because disagreement among professional caregivers about the goal of care can increase liability.

Withholding and withdrawing life support are legally justified primarily by the principles of informed consent and informed refusal. These principles were applied in the Karen Ann Quinlan and Nancy Cruzan cases. In the Quinlan case, the New Jersey Supreme Court upheld a patient’s right to refuse mechanical ventilation. In the Cruzan case, the Missouri Court held that sufficient evidence of the patient’s wishes had been offered and made the ruling to permit tube withdrawal. These cases were milestones because they allowed the families, not the physicians, to determine
which treatments were appropriate and which were futile. The Patient Self-Determination Act of 1990 further opposed the culture against the traditional medical paternalism and fostered patients' rights.78

**The Nurse Caregiver**

In most settings, the nursing staff is involved in the terminal sedation or weaning process. Nurses must be provided with the proper educational training to rectify knowledge and skill deficits and to provide nurses the opportunity to seek alternative employment in another setting if they do not feel comfortable with palliative sedation or the terminal weaning process.79,80 Nurses involved in caring for these patients should be allowed to abstain from doing so until they feel comfortable with the process.

It may also be helpful for the nurse to have education and support regarding personal death awareness. Personal death awareness is defined as one's comfort with death and can be affected by personality, cultural, social, and spiritual belief systems. The nurse must be allowed to adapt to caring for dying patients, which may require the nurse to explore, experience, and express his or her feelings regarding death. If the nurse is not allowed to explore his or her personal beliefs, this may result in inappropriate defense mechanisms, such as emotional distancing or avoidance and withdrawal from dying patients and families.

Cumulative loss is experienced by nurses working with patients with life-threatening illnesses. Cumulative loss can be described as a succession of losses experienced by nurses who care for dying patients. Systems of support must be in place to help the nurse deal with loss. Palliative care recognizes that no one can do this work alone. Nurses at the bedside can be supported by professionals from many other disciplines, including social workers, chaplains, counselors, advanced practice nurses, and physicians. Nurses who work with patients requiring palliative sedation and terminal weaning are at increased risk of burnout if not intimately involved with the team decision-making process. It is vital that these nurses be involved in the decision-making process, because they have high responsibility but often low autonomy. Bedside nurses are intimately involved in palliative sedation and the terminal weaning process, but, if left out of decision-making processes such as the team planning and family conferences, they are denied the information needed for effective counseling at the bedside.81 There must be a formal and informal support system as well as education in end-of-life care, spiritual support, and individual support as needed.

An interdisciplinary team meeting after death in these cases can function as both a learning experience and a debriefing process. Working in an environment that recognizes the need for support and education for staff, and one that recognizes the importance of mentors and advance practice nurses, allows nurses to face these challenges as they arise.81

**Case Study Conclusions**

**CASE STUDY I**

**Mr. M—Conclusion**

After 5 days of aggressive attempts to reverse the delirium, a family meeting was held with all significant people present. The decision was made to provide palliative sedation for a trial of psychotropic drug discontinuation with the hope that the hyperactive delirium might reverse. The mother and significant other understood that sedation could be terminal but clearly agreed that Mr. M's distress was unbearable. The family opted for continued hydration, no parenteral nutrition, chaplain and counseling support, and a course of midazolam. Attempts to decrease the midazolam dose 2 days later resulted in renewed agitation, so the dose was returned to maintenance level and the patient died the next day with his loved ones at his side. The family was referred to bereavement services in the state where they live.

**CASE STUDY II**

**Mr. Z—Conclusion**

The ethics team reviewed the case to determine the patient's capacity and understanding of terminal weaning. The nurse was also concerned that withdrawing life support from this awake, alert patient would appear “Kevorkian-like” or give the impression of euthanasia. The ethics team believed that the patient had made his wishes clear. He did not want to continue his life if it meant being dependent on mechanical ventilation. The patient's wife was supportive of his wishes, as were his two adult children. The team's conclusion and recommendation was to support the patient's wishes and the physician's decision to withhold further treatment, dialysis, and to withdraw ventilator support. The ethics team also felt the patient was making an informed decision.

A decision was reached between the ICU attending physician and the patient that the ventilator would be withdrawn the next morning. The following day the patient had his family at his bedside while the ventilator adjustments were made. He was sedated, and comfort measures were taken. The patient was made comfortable and within 10 minutes after weaning from the ventilator he died peacefully with his family, physician, and nurse at the bedside.

**Conclusion**

In today's ICU environment, advances in technology that are designed to prolong life have outpaced those designed to return patients to a reasonable quality of life.82 This disparity has
caused ICU nurses to view death as an acceptable outcome, maintaining palliative care and symptom management, and ensuring a dignified, tolerable death with the more traditional goals of curing disease, restoring health and function, and promoting life and survival. Nursing professionals in the ICU should train new nurses in the skills required to withdraw and withhold care. These skills do not come easily; a concerted effort should be made to provide proper training to ensure patients a painless, dignified, peaceful death.

Although many may disagree about what a “good death” is, there is general agreement about what is a “bad death.” Palliative sedation and terminal weaning are ethical and realistic interventions in a percentage of dying patients whose symptoms remain unbearable despite aggressive palliative interventions. The concerns and challenges appear to be related to the lack of consistency in providing care skillfully across all settings. The confusion between slow euthanasia and sedation remains, as does a lack of agreement on palliative sedation for existential suffering. The ability to determine refractoriness of symptoms is complicated by the lack of palliative care experts in all settings as well as the continued challenge of accurately predicting time to death. When all patients have access to nurses and physicians with specialized training in palliative sedation and terminal weaning, the dying process will improve significantly.

Appendix 24-1
End-of-Life Protocol

Introduction

The Intensive Care Unit (ICU) healthcare team provides complex medical and nursing interventions to stabilize and improve the physical status of critically ill patients. However, there are frequent situations in which the patient cannot be stabilized, their status cannot be improved or continued life-sustaining interventions would be medically inappropriate.

The End-of-life Protocol is a guide and educational tool for the ICU healthcare team. Consequently the patient will benefit from expert, competent, compassionate, consistent end-of-life care.

The End-of-Life Protocol should be initiated subsequent to a patient care conference and a written DNR order.

Definitions

ICU healthcare team—The ICU healthcare team is multidisciplinary and the participants vary according to the needs of the patient or family. Members may include: physicians, nurses, social worker, respiratory therapist, ethicist, dietician, physical therapy, pharmacist, chaplain, and others depending on the patient’s physical and mental status.

Intensive care physician—The Intensive Care Physician supervising the initiation of the End-of-Life Protocol will sign the End-of Life Orders and will be readily available to consult with the nurse and family during the patient’s end-of-life care.

Contact alternate physician—If the Intensive Care Physician is unavailable during the patient’s end-of-life care, the Intensive Care Physician will indicate a physician that will assume supervision of the patient’s care. This physician will be known as the Alternate Physician Contact and will be identified on the End-of-Life Orders by name and pager number.

Comfort measures—Comfort measures are interventions that ease the patient’s discomfort. Comfort measures may include: regulation of hypothermia or hyperthermia, oral care, basic hygiene, music therapy, control of pain and sedation.

Family—Family includes spouse, mother, father, sibling, guardian, or any significant other to the patient.

Patient care conference—The family and or patient meets with the Intensive Care Physician, Attending Physician, nurse, social worker and other appropriate members from the ICU healthcare team to discuss the patient’s medical status. The goal for the Patient Care Conference is to develop a plan of care that may include the End-of-Life Protocol.

Plan of care—The plan of care gives direction and prioritizes the care the patient receives.

Signs and symptoms of discomfort—Signs and symptoms of discomfort include, but are not limited to: agitated behavior, altered cognition, anxiety, autonomic hyperactivity, confusion, coughing, dyspnea, grimacing, increased work of breathing, irritation, moaning, pain, restlessness, tachycardia, splinting, tenseness, self-report of discomfort, perspiration, stiffness, trembling and tachypnea.

When appropriate—The terms “when appropriate” or “appropriate” in reference to the End-of-Life Protocol defines a time when the patient, family and ICU healthcare team are present and prepared to initiate the steps outlined in the Protocol. The timing for Protocol initiation will accommodate the needs of the patient and family.

Purpose

The purpose for the End-of-Life Protocol is to guide the ICU healthcare team, promote consistency of care, and improve the quality of care provided during the patient’s end-of-life.

Goal

The goal for the End-of-Life Protocol is to maximize patient comfort and dignity without prolongation of life, extension of the dying process or hastening the dying process.
Objectives

The End-of-Life Protocol and care may include the following actions:

- Create a quiet, calm, restful atmosphere with minimal medical devices and technology in the patient’s room.
- Remove or discontinue treatments that do not provide comfort for the patient.
- Provide controlled and comfortable end-of-life care for the patient.
- Promote patient comfort with a variety of approaches including medications.
- Provide physical, psychological, social, emotional, and spiritual resources for the patient and family.
- Educate and support the patient’s family regarding the progression of end-of-life care and the interpretation of the clinical signs and symptoms the patient may experience.
- Assist the family in meeting their needs and the patient’s needs for communication, final expressions of love, and concern.
- Assist the family in fulfilling familial, cultural or religious death rituals.

NURSING ADMINISTRATION OF MIDAZOLAM AND PROPOFOL TO NON-INUTUBATED PATIENTS FOR PALLIATION OF SEVERE INTRACTABLE SYMPTOMS FOR TERMINALLY ILL CANCER PATIENTS ON THE PALLIATIVE CARE UNIT

PURPOSE
To establish an institutional standard for administering and monitoring sedation using midazolam and/or propofol for palliation of severe intractable symptoms for terminally ill cancer patients on the Palliative Care unit (PCU). This protocol does not address the use of midazolam or propofol or other benzodiazepines for conscious sedation or anesthesia.

GENERAL INFORMATION
Administration of anesthetic agents by RNs to non-intubated patients be practiced in accordance with the following guidelines. These are systematically developed recommendations that will provide nurses with criteria for making decisions about the administration of anesthetic agents that are consistent with evidence-based practice guidelines and the position statement of the Texas Board of Nurse Examiners on Anesthesia by RNs.

SCOPE
The Texas Board of Nurse Examiners states: "The clinical effects for patients receiving anesthetic agents may vary widely within a negligible dose range. Because of the danger of unintended deep sedation and/or general anesthesia with pharmacologic agents classified as "anesthetic" agents, the Board advises caution for registered nurses who are not qualified anesthesia providers in administering such agents in non-intubated patients. Both nurses and facilities should consider evidence-based practice guidelines put forth by the respective specialty group(s) for a given practice area in developing the appropriate guidance for the RN in the specific practice setting."

The procedure covers the administration of midazolam or propofol continuous infusion for the purposes of palliation of severe and unendurable symptoms, such as agitated
delirium, severe dyspnea, or active severe bleeding. This procedure applies to terminally ill cancer patients under the care of the Palliative Care service. These symptoms can be a source of great distress to the patient and family. Sedation is a widely used intervention by Palliative Care providers, in the U.S. and internationally, to control symptoms in these rare circumstances. The practice is widely supported by the Palliative Care Literature. Midazolam is the most frequently reported agent in use. Propofol is also an agent of choice due to its speed of onset, easy titration and easy reversibility. See also "Palliative Sedation Policy for the Symptom Control and Palliative Care Service".

**DEFINITIONS**

**Palliative sedation** (previously known as terminal sedation) is defined as the monitored use of medications (midazolam or propofol) that induce sedation to control refractory and unendurable symptoms near the end of life when the control of these symptoms is not possible using less aggressive measures. The purpose is to control symptoms and not to hasten death.

**Refractory Symptoms** are defined as those symptoms that cannot be adequately relieved or controlled despite aggressive use of usually effective therapies (e.g. medications, other interventions), and seem unlikely to respond to further invasive or non-invasive therapies in a timely way without excessive or intolerable side effects/complications.

**Continuous infusion administration** is defined as the administration of medication directly into an intravenous or subcutaneous site continuously by measured and metered dosage using an infusion pump.

**Midazolam** is a very short acting benzodiazepine (onset of action within 3-5 minutes after intravenous injection with peak effect seen in 20-60 minutes), used most frequently as an induction agent for general anesthesia or to provide conscious sedation during brief invasive diagnostic procedures. The drug is given by IV/SQ infusion with starting dose of 0.5-1mg/Hr.

**Propofol** is an intravenous sedative hypnotic agent useful in the induction and maintenance of general anesthesia, and in sedation of mechanically ventilated patients. The onset of action is given by continuous infusion with a staring dose of 0.15mg/kg/Hr.

**ORDERING/ADMINISTERING PROCEDURES**

**PRIVILEGES**

1. The Department of Palliative Care and Rehabilitation Medicine will recommend the award of privileges for Palliative Care Staff physicians for palliative sedation on the PCU using midazolam and propofol. This privilege covers evaluation of terminally ill patients for the need for the procedure, and the issuance of orders for palliative sedation.

2. Nurses who have successfully completed the Palliative Sedation Competency may administer palliative sedation as described by the Palliative care physician.
3. If ordered for palliative sedation, each of the following criteria must be met in order for midazolam or propofol to be administered:

   Irreversible advanced disease with death appearing imminent (within days to weeks).

   Severe unendurable symptoms.

   Refractory symptoms to conventional interventions.

   Anti cancer therapies have been discontinued and all interventions are tailored to patient comfort.

   DNR order in place.

   Meets medical necessity criteria based on medical judgment of a palliative care physician.

4. If ordered for palliative sedation, the patient and/or family receive education about the goal of palliative sedation, which is to control intractable symptoms rather than hasten death. Efforts are made to develop consensus among family members concerning the goal of this intervention. Informed consent is obtained prior to the procedure and documented in the patient medical records. If the patient is disoriented or comatose, the consent may be obtained from the individual having Medical Power of Attorney. A final review by members of the Clinical Ethics Service may be offered to the patient and/or family prior to implementation.

   These medications have the potential to induce conscious sedation and/or general anesthesia, and must be monitored accordingly. "Palliative Sedation Policy for the Symptom Control and Palliative Care Service".

5. a. Midazolam or propofol continuous infusions, administered by subcutaneous or intravenous routes, may be used for the control of refractory symptoms in the PCU (Palliative Care Unit) using Palliative Sedation Physician Orders.

   b. If midazolam or propofol continuous infusion is being considered for the management of refractory symptoms, a palliative care consultation should be established and if considered appropriate the patient will be moved to the palliative care unit where less aggressive symptom management trials may be attempted by the palliative care team. The decision to institute sedation using continuous IV midazolam or propofol should be made by the palliative care attending and documented in the patient medical records.

   c. An intravenous (IV) or subcutaneous (SQ) line is established prior to the administration of midazolam continuous infusion. An intravenous line is established before starting propofol.

   d. Assess and document vital signs prior to administration of drug.
e. Maintain aspiration precaution, provide mouth and eye care, maintain bowel and bladder care and avoid pressure sores by turning the patient regularly from side to side.

f. Continue opioids, oxygen and other medications as needed for comfort measures.

g. A patient receiving a midazolam or propofol by continuous infusion is monitored for respiratory depression and sedation. Patient monitoring requires assessment of level of consciousness and respiratory rate as medically appropriate using the Palliative Sedation record

h. Midazolam or propofol is never pushed or bolused. Administer at a continuous rate only in the Palliative Care Unit, with titration (increases or decreases in dose) no more frequently than q1h.

| STARTING ANALGESIA | 6. a. For Midazolam start at a dose of 0.5-1mg/hr by continuous IV or subcutaneous infusion

|            | b. Use propofol at a starting dose of 0.15mg/kg/hr by continuous IV infusion.

|            | c. Keep flumazenil 0.2 mg IV handy for immediate reversal of respiratory depression from infusion.

| MONITORING | 7. a. The registered nurse managing the care of the patient receiving IV or SQ palliative sedation shall have no other responsibilities that would leave the patient unattended until the medication is titrated to adequate symptom control. The RN will check respiratory rate as medically appropriate.

|            | b. Use the smallest effective dose to control symptoms.

|            | c. The order for palliative sedation should be reviewed daily by a Palliative Care physician and renewed if necessary.

Primary Diagnosis: Admitting Diagnosis:

Allergies:

Provider's signature indicates all orders with boxes checked are activated.

Transitional Care:

- [ ] Discontinue neuromuscular blockade agents prior to weaning ventilator.
- [ ] Discontinue all tests and laboratory studies.
- [ ] Remove all monitoring equipment from the patient and patient's bedside except for the ECG.
- [ ] Suspend arrhythmia detection at bedside and central station.
- [ ] Suspend or decrease all auditory alarms at bedside and central station.
- [ ] Discontinue medications and fluids when appropriate:
  - Hydration
  - Vasoactive medication
  - other
- [ ] Discontinue mechanical support devices:
  - Dialysis
  - IABP
  - other
- [ ] Assess and monitor the patient for signs and symptoms of discomfort.
- [ ] Liberalize visitation

Medications:

- [ ] Morphine drip at _________ mg/hr or [ ] Fentanyl drip at _________ mcg/hr.
- [ ] Lorazepam drip at _________ mg/hr or [ ] Midazolam drip at _________ mg/hr.
- [ ] Other medication drips (i.e. benzodiazepine, barbiturate, propofol):
  - _________ mg/mcg/kg/hr
  - _________ mg/mcg/kg/hr
- [ ] For signs of patient discomfort give IV bolus of medication equal to drip rate every 3 minutes until patient is comfortable.
- [ ] To maintain patient comfort, increase drip rate up to 50% of prior rate.
- [ ] Contact physician and charge nurse regarding patient status.

Ventillator:

- [ ] Initiate ventilator wean once patient appears comfortable.
- [ ] Oscillatory Ventilation converted to conventional ventilator.
- [ ] Initial Ventilator setting: FIO2 _________ Bilevel – High PEEP _________ Low PEEP _________
  - PS
  - IMV
  - PEEP
  - PS
  - IMV
  - PEEP
- [ ] Reduce all ventilator alarms to minimum settings.
- [ ] Transition FIO2 to 0.21 and PEEP to zero.
- [ ] Assess for signs and symptoms of patient discomfort while decreasing the tidal volume and rate.
- [ ] When the patient is comfortable on minimal ventilator support, select one:
  - extubate to room air
  - T-piece
  - remain on ventilator

Key Points

- Complementary therapies improve quality of life in patients with advanced cancer.
- Complementary therapies reduce physical, psychosocial, and spiritual symptoms and provide comfort.
- Nurses bring hope and power to patients and families through education and guidance to safe complementary therapies.

Case Study

Mary, a 64-Year-Old Woman with Stage IV Lung Cancer

Mary was a 64-year-old vivacious, beautiful woman with a zest for life, a wonderful sense of humor, and a terrific Welsh accent. She appeared much younger than her stated age. She was born in Wales and immigrated to the United States at the age of 23. She was happily married for 29 years and had a 23-year-old son, whom she adored. Mary was a strong woman who had managed to stay sober in Alcoholics Anonymous one day at a time for 10 years, and who was able to stop smoking after 35 to 40 years of smoking. She had numerous friends and was cherished by many.

Mary was in good health until a tumor was discovered in 1998 on a routine chest radiograph. She had a right upper lobectomy and was diagnosed with non–small cell lung cancer. No follow-up treatment was done. She was devastated by the diagnosis, but once she recovered from the surgery, she seemed to be back to her old self. In the fall of 1999, Mary suffered from several bouts of pneumonia, shortness of breath, sore throat, and fatigue. In summer of 2000, some cervical lymphadenopathy was noticed; positron emission tomography (PET) scanning showed multiple lymph node involvement, including right supraclavicular, right adrenal, right paraspinal, right diaphragmatic, and mediastinal spread. She sought out a second opinion and transferred her care to a major cancer center, where biopsy of the right supraclavicular lymph node confirmed metastatic non–small cell lung cancer.

The nurses at the cancer center informed Mary about the Integrative Medicine Service (IMS). Mary came to IMS several weeks after her biopsy. She had a consultation with the clinical nurse specialist (CNS), who also administered several of the therapies to inpatients and outpatients. The CNS explained that all of the therapies and classes were focused on stress management, symptom control, and improving quality of life. The verbal assessment of the patient by the CNS
revealed the following symptoms: tenderness in the right lower neck, anxiety, fatigue, nausea, and depression. The CNS discussed the various therapies and asked the patient what she thought she might like. It was decided to begin with acupuncture to help reduce the neck pain and the nausea. Mary had a few sessions of acupuncture and was pleased to see a reduction in neck pain and nausea. A few weeks later, Mary came in and talked about how worried she was about the tumor and her symptoms. She was asked to rate her symptoms on a scale of 1 to 10. She reported nausea 7/10, fatigue 9/10, anxiety 9/10, and depression 5/10. It was decided to give reflexology as an attempt to reduce her symptoms. After the 60-minute reflexology session, Mary was smiling and excited to see the rather rapid reduction of her symptoms as she rated nausea 1/10, fatigue 1/10, anxiety 0/10, and depression 0/10.

The following week, Mary reported that her treatment of chemotherapy was to be given the following week and she was experiencing a great deal of anxiety and muscle tension. A light to moderate medical massage was given, with reported relief of anxiety and muscular tension. The following week, Mary came to IMS the day after her first chemotherapy. She reported fatigue 7/10, anxiety 8/10, depression 6/10, and some pain 5/10 in her upper back. She was given again a light to moderate massage with the resulting reduction of fatigue 1/10, anxiety 0/10, depression 3/10, and pain 2/10. She left smiling and said, “This was a great way to end my day.”

Mary continued to come weekly to IMS as she received her chemotherapy. She reported more fatigue and cried at times about her son, her thinning hair, wondering if there would be a future, and being less able “to do life.” Because she was weaker and had very low platelet counts, reflexology was more the therapy of choice, with the resulting relief of anxiety and some of the fatigue. She reported, “I feel like I could go out dancing.” Mary’s disease course was complicated by shortness of breath, chest pain from a pulmonary embolus, a deep vein thrombosis (DVT) in the right neck, and a DVT of the left lower leg. She required hospitalization and was very frightened. Reflexology and massage were contraindicated, but Reiki was offered. Mary responded beautifully to Reiki; as her anxiety decreased, she reported, “You are my angels that help me get through these tough times.”

Mary was discharged after the placement of a Greenfield filter to prevent further movement of emboli and was started on the anticoagulant Fragmin. She returned to IMS to learn meditation and attended the chair aerobics class to learn exercises to help decrease breathlessness and fatigue and to increase her endurance for everyday activities.

Mary did well for another month but then it became clear that her disease was progressing with the development of pleural effusions, chest pain, and increasing shortness of breath. She required constant nasal oxygen and wore a Fentanyl patch for her chest pain. Mary eventually needed to be admitted again, and this time it was for the last time. IMS saw her frequently and was able to offer her the soothing benefits of light touch Reiki and music therapy. Often, both were offered at the same time. The nursing staff was grateful that the IMS team came and could always offer Mary something that made her feel better. Mary never declined the offer of these services, always had a smile when IMS appeared at her hospital door, always nodded yes, and raised her weakened hand, beckoning us to approach her bedside. Her husband and son, often in attendance, were taught some of the Reiki touch techniques and were encouraged to join in the singing and gentle drumming of the music. The last words that IMS staff heard from Mary’s lips were, “My angels.”

After reading this chapter, the reader should begin to understand the rationale for the choices that Mary and her caregivers made as she moved through the last stages of her life.

--

**Introduction to Complementary and Alternative Therapies**

There is worldwide use of complementary and alternative medicine (CAM) by cancer patients for many reasons (Table 25–1), but many of the oncologists and nurses that provide care for cancer patients have limited or no knowledge of these therapies or their benefits versus risks. Complementary medicine has become an important aspect of palliative and supportive cancer care.³ The management of debilitating physical

symptoms, particularly in terminally ill patients, is integral to good palliative care. When curative treatment is no longer an option, the emphasis of care shifts to palliation and symptom management. Comfort measures become the main focus.2

Many patients in the advanced stages of cancer seek treatments outside conventional medicine in hopes of a cure and better management of the debilitating physical symptoms. Some CAM therapies can improve quality of life, such as management of pain, dyspnea, nausea and vomiting, fatigue, anxiety, depression, insomnia, and peripheral neuropathy, whereas others may be potentially harmful or useless. It is difficult, if not impossible, for most readers to distinguish between reputable treatments and promotions of unproven alternatives pushed by vested interests. CAM is complicated because of its unfamiliar terminology, large numbers of available therapies, and the controversial anecdotal stories versus good research studies. It is confusing for patients, families, doctors and nurses to find their way through to the most effective and safest choices.

In this chapter, the focus is on the most helpful complementary therapies. Cancer is used as a model of chronic progressive disease. Most of the literature and research on CAM is related to cancer but can be expanded to cardiac, liver, and lung disease, diabetes, and other illnesses. Evidence-based complementary therapies are shown to affect in safe ways patients’ physical, emotional, and spiritual well-being. Individuals who can participate in their care in the last stages of their illnesses are often more hopeful and positive than those who are passive participants. Patients in the advanced stages of their disease can participate in their care by knowing that they have options to promote comfort and quality of life. It is the role of nurses to educate themselves, their patients, and families to assist in the critical decision-making of CAM.

The goals of this chapter are (1) to define terms related to CAM; (2) to list, define, and describe the benefits and risks of the most common CAM therapies; (3) to emphasize the most beneficial evidenced-based complementary therapies along with the supportive research; and (4) to describe the role of the nurse as an educator, researcher, and clinical practitioner in the setting of CAM. Patients look to their nurses to guide them to make informed and safe complementary therapy choices. Nurses can bring hope and power to their patients and families by teaching, supporting, and encouraging the use of safe complementary therapies when indicated.

Definitions

CAM can include anything that is not conventional Western medicine or found in hospitals.3,4 CAM is a group of diverse medical and health care systems, practices, therapies, and products that are not presently considered to be part of conventional medicine. “They range from adjunctive modalities that effectively enhance quality of life and promising antitumor herbal remedies now under investigation to bogus therapies that claim to cure cancer and that harm not only directly, but also indirectly by encouraging patients to avoid or postpone effective cancer care.”5 The list of what is considered to be CAM changes continually, as therapies that are proven to be safe and effective become adopted into conventional health care.

Although they are grouped together, complementary and alternative therapies are very different. Complementary therapies are used together with conventional care. They are not promoted as cancer cures but are used as soothing, noninvasive therapies to provide comfort and increase the quality of life to patients (Table 25–2). The goals of complementary cancer care are to promote relaxation, reduce stress and anxiety, relieve pain and other symptoms, reduce adverse effects of conventional therapies, and improve sleep.1 An example of a complementary therapy is the use of reflexology to help to lessen patients’ anxiety as they await a painful procedure.

In contrast, alternative therapies are used in place of surgery, chemotherapy, and radiation therapies. They are invasive, biologically active, and unproven and are promoted as viable cures and alternatives to be used in place of mainstream cancer treatments.6 Some examples of alternative therapies are Laetrile, dietary cancer cures, oxygen therapy, and biomagnetics. There is not a single alternative intervention (as opposed to mainstream therapies) that has been demonstrated to constitute an effective cure for cancer.1 Alternative therapies can misguide, raise false hopes, and financially exploit patients and may be associated with significant risks. They may prevent patients from seeking known, helpful medical oncological interventions.7

Integrative oncology medicine promotes the use of evidence-based complementary therapies along with mainstream cancer treatments. At a major comprehensive cancer center, Memorial Sloan-Kettering Cancer Center (MSKCC) in New York

City, Integrative Medicine practitioners of massage, reflexology, Reiki, meditation, acupuncture, art therapy, and music therapy work with inpatients who have been self-referred or referred by doctors, nurses, or other hospital professionals. Outpatients are offered these same therapies along with nutritional counseling, yoga, Tai chi, Qigong, and other exercise classes.

History

The history of medicine is filled with descriptions of persons using herbs, potions, and physical and spiritual manipulations to heal the sick. Traditional medicine came into being in the United States in the late 1890s when physicians began to develop the science of medicine, with a focus on cure. Anything other than the allopathic physician using science-based diagnosis and prescribing tested medicines began to be considered quackery. The healer became passé. Recently, however, there has been a resurgence of interest in the use of herbal and other CAM therapies that fall outside mainstream medicine. People are living longer with chronic diseases, cancer being one of them. Patients look to CAM therapies to help with quality of life, to allow them to participate in their own self-care, and to provide a glimmer of hope and maybe a cure. Physicians and nurses are voicing concerns that patients are being misled about CAM therapies, are wasting their time and money, are putting themselves in harm’s way, and are not reporting the use of these therapies to the medical team.

The increasing use of CAM by the American people prompted the United States Congress to establish in 1992 the Office of Alternative Medicine (OAM) as part of the National Institutes of Health (NIH). In 1998, the name was changed to the National Center for Complementary and Alternative Medicine (NCCAM), and a larger budget was assigned. NCCAM’s mission is to explore complementary and alternative healing practices in the context of rigorous science, to train CAM researchers, and to inform the public and health professionals about the results of CAM research studies.

Prevalence

General Population

The use of CAM by the general population in the United States is common, widespread, and on the rise. In a national health interview survey conducted by the Centers for Disease Control and Prevention (CDC) in 2002, use of CAM therapies among U.S. adults was 36% when prayer was excluded and 62% when prayer for health reasons was included. Some publications cite prayer as a CAM therapy. Prayer has been with us for a long time and is not considered to be a CAM in the strict sense of the term; it is excluded from further discussion as a CAM therapy in this chapter. Other findings of the CDC study were that women are more likely than men, black adults more likely than white or Asian adults, persons with higher educations more likely than those with lower education, and those who have been hospitalized in the past year more likely than those who have not been hospitalized to use CAM.

Cancer Population

Among cancer patients, rates of CAM use are usually higher than in the general population. But Ernst and Cassileth, in 1998, found that the average use in 26 surveys from 13 countries was 31.4%, ranging from 7% to 64%. They believed that lack of specificity and inconsistent definitions of CAM to have contributed to this variability. For example, some studies included counseling, group therapy, prayer, wellness regimens, and self-help efforts as CAM, whereas others counted these as mainstream therapies. Another study reported 63% use of CAM therapies by adult cancer patients enrolled in an National Cancer Institute (NCI) clinical trial. Higher use among women and among patients with higher education was also observed. Sixty-two percent of the patients in this study reported that they would have liked to talk to their physicians about the use of these therapies, but 57% said that their physicians did not ask them about CAM therapies.

Rural Cancer Population

One study looked at the use of only complementary therapies in a rural cancer population. Eighty-seven percent of the patients were using at least one complementary therapy, most commonly prayer, humor, support group, and relaxing music and visualization. Again, women were found to be more interested in CAM, but education and income did not seem to make a difference in this population.

Comprehensive Cancer Center

In an outpatient clinic in a comprehensive cancer center, 83% of the patients had used at least one CAM therapy. When psychotherapy and spiritual practices were eliminated, 68.7% had used at least one other CAM therapy. Use of multiple CAM therapies with conventional treatment was widespread, disclosure of CAM to the physician was low, and seeking information about CAM was high.

Breast Cancer Patients

The prevalence of CAM among breast cancer patients varies but is higher than in the general population. New use of CAM after surgery in patients with early-stage breast cancer (28.1%) was thought to be a marker for greater psychosocial distress and worse quality of life. It was suggested that physicians take note of such usage and evaluate patients for anxiety, depression, and physical symptoms. The prevalence of CAM use among breast cancer survivors in Ontario, Canada, was 66.7% and was mostly associated with the hope of boosting the immune system. Women with breast cancer tended to use more CAM, compared with patients with other malignancies
lished in the New England Journal of Medicine20 that some pain and anxiety. There is some evidence from letters published in the pediatric population for the symptoms of disease were included.17 These higher percentages may be indicative of the patients’ high level of distress, but they may also indicate the seeking of hope and attempts to control their situations.

**Pediatric Population**

CAM therapies are infrequently studied in pediatric populations. Parents of patients were surveyed in British Columbia between 1989 and 1995. CAM was found to be used by 42% of the patients.18 Relaxation techniques and imagery were used to reduce chemotherapy side effects in children and adolescents.19 At MSKCC, reflexology, imagery, and music therapy are successful used in the pediatric population for the symptoms of pain and anxiety. There is some evidence from letters published in the New England Journal of Medicine20 that some parents choose alternative approaches, where evidence of efficiency is lacking, rather than conventional evidence-based therapies. Use of conventional and alternative therapies simultaneously is also of concern, because there could be a harmful reaction between the two. The possibility of simultaneous use calls for education and discussion with the parents and families about known risks and the recognition that “doing everything” may be harmful.21

**Ethnic Differences**

There appears to be a relation between ethnicity and CAM use. In a diverse population in Hawaii, CAM use was highest among Filipino and Caucasian patients, intermediate among the Native Hawaiians and Chinese, and significantly lower among Japanese patients.22 The preferences were as follows: Filipinos, religious healing or prayer; Japanese, vitamins and supplements; Chinese, herbal therapies; Native Hawaiians, religious healing, prayer, vitamins, supplements, massage, and bodywork; and Caucasians, vitamins and supplements along with support groups and homeopathy. A study by Lee and associates23 on the use and choices of CAM by women with breast cancer in four ethnic populations revealed that Blacks most often chose spiritual healing, Chinese chose herbal remedies, Latinas chose dietary therapies and spiritual healing, and Whites chose dietary methods and physical methods such as massage and acupuncture. Another study of Navajo patients revealed that 62% used Native healers but did not see a conflict between the use of a native healer and use of conventional medicine.24 These studies suggest that culture can influence CAM choices and should be considered when caring for patients.

**Elderly**

Another study25 found CAM use in older adults (65 years of age and older) to be 64%. This study also revealed that only 35% of all self-reported supplements actually were documented in the patient’s chart by the physician. This created potential risks, because some patients were found to be taking CAM with anticoagulant properties along with prescribed anticoagulants.

**Cost**

Most insurance companies do not reimburse for CAM. The cost of CAM may prevent many patients from receiving these therapies. There is a movement before the U.S. Congress to begin to acknowledge the value of these therapies and to reimburse for them. It is suggested that patients check with their insurance companies to see whether use of CAM can be reimbursed. There is hope that reimbursement will be soon forthcoming.

**Overview of Complementary and Alternative Therapies**

CAM therapies have been grouped into five major domains by the NCCAM: (1) alternative medical systems (traditional Chinese medicine, ayurvedic medicine, homeopathic medicine, naturopathic medicine, Native American medicine, and Tibetan medicine); (2) mind–body interventions (meditation, focused breathing, progressive muscle relaxation, guided imagery, creative visualization, hypnosis, biofeedback, music therapy, and art therapy); (3) biologically based therapies, nutrition, and special diets (e.g., probiotics, megavitamins, and orthomolecular therapies, metabolic therapies, individual biological therapies such as shark cartilage) and herbal medicine; (4) manipulative and body-based methods (massage, aromatherapy, reflexology, acupuncture, Shiatsu, polarity, chiropractic medicine, yoga, and exercise); and (5) energy therapies (Reiki, Qi gong, and therapeutic touch). The currently popular therapies are discussed in the following sections. Many of these methods are not proven, whereas others have been documented as helpful complementary therapies.

Counseling, group therapy, prayer, and spirituality, which we already know to be very helpful to cancer patients, are not included in this CAM chapter, because many view them as part of mainstream therapies.

**Alternative Medical Systems**

Instead of disease-oriented therapies, ancient systems of healing were based on attributing health, illness, and death to an invisible energy or life force and the suggestion of an interaction between the human body, human kind, the spirit world, and the universe. In the earliest of times, there seemed to be a link between religion, magic, and medicine. This is in contrast to modern Western medicine, which is focused on the cause and curing of the disease. These alternative medicine systems are briefly discussed in this chapter because they are followed by many people today. The best known examples of alternative
Traditional Chinese Medicine

The cornerstone concept in Chinese medicine is qi (life force), which is energy that flows through the body along pathways known as meridians. TCM views people as ecosystems in miniature. Any imbalance or disruption in the circulation of Chi or qi (pronounced “chee”) is thought to result in illness. Restoration of one's health is therefore dependent on returning the balance and flow of the life force. A TCM diagnosis is based on examination of the person’s complexion, tongue, radial pulse, and detection of scents in bodily materials. Treatment is geared toward correcting imbalances or disruptions of the qi, primarily with herbal formulas and acupuncture.

Acupuncture is one of the best known forms of CAM. It is one component of TCM. It is based on the belief that qi, the life force, flows through the human body in vertical energy channels known as meridians. There are 12 main meridians, which are believed to be dotted with acupoints that correspond to every body part and organ. To restore the balance and flow of qi, very fine disposable needles are inserted into the acupoints just under the skin. Other stimuli can be used along with acupuncture, such as heat (moxibustion), suction (cupping), external pressure (acupressure), and electrical currents (electroacupuncture). The biological basis of qi or meridians has not been found, but it is thought that acupuncture needling releases endorphins and other neurotransmitters in the brain. There is good evidence in the oncology literature that acupuncture helps control pain and nausea and vomiting. There is current research on its possible effectiveness for fatigue and dyspnea. Risks associated with acupuncture include mild discomfort or occasionally a drop of blood and or a small bruise at the site of the insertion, but they can include more serious problems, such as an infection or (in the most extreme case) a pneumothorax, which is rare and depends on the training and experience of the acupuncturist.

Ayurvedic Medicine

The term Ayurveda comes from Sanskrit words ayur (life) and veda (knowledge) and is about 5000 years old. Ayurvedic medicine is based on the idea that illness is the absence of physical, emotional, and spiritual harmony. Many of the basic principles are similar to those of Chinese medicine. Ayurveda is a natural system of medicine that uses diet, herbs, cleansing and purification practices, meditation, yoga, astrology, and gemstones to bring about healing. It sees causation of disease as an accumulation of toxins in the body and an imbalance of emotions. It prescribes individualized diets, regular detoxification, cleansing from all orifices, meditation, and yoga as some of the therapies. There is no scientific evidence that Ayurvedic medicine healing techniques cure illness.

Homeopathic Medicine

Homeopathy is a medical system that was devised by Samuel Hahnemann 200 years ago, when the causes of diseases, bacteria and viruses, were unknown and little was understood about the workings of the bodily organs. The thinking was that symptoms of ill health represent expressions of disharmony within the person and attempts of the body to heal itself and to return to a state of balance. It is the person, not the disease, that needs treatment. The treatment of disease is based on the principle, “Like cures like.” Homeopathic medicines are made by taking original substances from plants, animals, and minerals and highly diluting them. It is believed that the body's own healing ability is stimulated by these medicines. Homeopathic medicines are sold over the counter without prescription. They are so dilute that they are thought to have no side effects and at the same time to be ineffectual for medical conditions, including cancer-related conditions.

Naturopathic Medicine

Naturopathy is more of a philosophical approach to health than a particular form of therapy. It is an alternative medical system that attempts to cure disease by harnessing the body's own natural healing powers, and restoring good health and preventing disease. Rejecting synthetic drugs and invasive procedures, it stresses the restorative powers of nature, the search for the underlying causes of disease, and the treatment of the whole person. It takes very seriously the motto, “First, do no harm.” Naturopathic medicine began as a quasipsiritual “back to nature” movement in the 19th century. European founders advocated exposure to air, water, and sunlight as the best therapy for all ailments and recommended spa treatments such as hot mineral baths as virtual cure-alls. This system relies on natural healing approaches such as herbs, nutrition, and movement or manipulation of the body. Most naturopathic remedies are considered harmless by conventional practitioners, but using naturopathy instead of conventional medicine is not wise.

American Indian Medicine

Native American medicine is a system of healing that is used as the primary source of medical care or in combination with
Western medicine. Physical illness is attributed to spiritual causes or evil spirits. Healing involves activities that appease the spirits, rid the individuals of impurities, and restore them to a healthful, spiritually pure state. The central figure in American Indian healing is the medicine man (healer, sorcerer, seer, educator, and priest), often called shaman. Shamans are trained spiritual healers who seek to drive the evil spirits out. Four healing techniques are practiced by Native Americans: purifying and purging the body through the sweat lodge, the use of herbs, involvement of shamanic healers, and symbolic rituals. Shamanistic methods included incantations, charms, prayers, dances, shaking of rattles, beating of drums, and sucking to remove disease. Native American healing is more spiritual and magical than scientific. There are anecdotal reports of healers curing diseases, but these have not been formally investigated.

The most important evidence of Native American influence on traditional American medicine is the fact that > 200 indigenous medicines that were used by one or more tribes have been listed in the Pharmacopeia of the United States of America.

Tibetan Medicine

Tibetan medicine views the human body as an ecological system, a microcosm directly related to the macrocosm of the world. It attempts to investigate the root causes of illness. The belief is that all of the material that makes up our universe is based on the qualities of five basic elements (earth, water, fire, wind, and space). It is understood through experience that natural environmental forces can influence the functioning of the human organism. The Tibetan doctor bases his practice of diagnosis on his own spiritual practice, intellectual training, and intuition. The Tibetan medical diagnosis is a result of the patient interview, observation of the urine, taking of the 12 pulses, looking at the sclera and surface of the tongue, and feeling for sensitivity on certain parts of the body. The treatment is similar to that used in Chinese medicine, especially herbs.

Mind–Body Interventions

Mind–body medicine uses a variety of techniques designed to enhance the mind’s capacity to effect change in bodily functions and symptoms. The ability to influence health with the mind is an extremely appealing concept, especially for patients who feel out of control. These are distraction techniques. To affirm the power of the individual, when a person can feel so powerless, is very attractive. Some good documentation supports the effectiveness of meditation, guided imagery, biofeedback, and yoga in stress reduction and the control of symptoms. The ability to control stress or other symptoms was expanded to the notion of controlling or curing the disease. There is no evidence that patients can control their disease through mental work. Furthermore, this approach can backfire on patients; they may feel guilty, responsible, and a failure as disease progresses despite their best mental efforts.

Meditation

Meditation is the intentional self-regulation of attention. It enhances concentration and awareness as the individual focuses systematically and intentionally on particular aspects of inner or outer experience. It allows one to stay present in the moment and without judgment. Historically, most meditation practices were developed within a spiritual or religious context with the goal of spiritual growth, personal transformation, or transcendental experience.

There are two categories of meditation: concentration and mindfulness. Concentrative methods cultivate one-pointedness of attention and start with mantras (sounds, words, or phrases repeated), as in Transcendental Meditation (TM). Mindfulness-based stress reduction (MBSR) practices start with the observation of thoughts, emotions, and sensations without judgment as they arise in the field of awareness. “Meditation can help individuals connect with what is deepest and most nourishing in themselves, and to mobilize the full range of inner and outer resources available to them.” Meditation has been helpful for terminally ill cancer patients. It has shown to be helpful in the relief of physical and emotional pain when integrated into a palliative care program. Many dying cancer patients discover that the calmness and quiet of meditation promotes a profound feeling of acceptance, well-being, and inner peace.

Walking meditation is appealing to those that cannot sit still. The focus might be on taking one step at a time, smelling the fresh air, taking in one breath at a time, or listening to the birds as one walks along.

Relaxation Techniques

Relaxation techniques are those simple techniques that, when learned by the patient, can promote relaxation. They include progressive muscle relaxation (contracting and relaxing muscle groups one at a time from head to toe), passive progressive muscle relaxation (no contraction of muscles, but focusing in the mind on sequentially relaxing groups of muscles), focused breathing (counting of breaths as one exhales, which can be used by itself or as an introduction to guided imagery).

Guided Imagery

“Imagery is the thought process that invokes and uses the senses: vision, audition, smell, taste, sense of movement, position, and touch. It is the communication mechanism between perception, emotion, and bodily change.” Imagery is a natural phenomenon in our lives that occurs all day long. For example, when we wake in the morning, we might imagine our day, where we will be going, what we will wear, what we will eat. Imagery is used as a distraction technique that allows the patient to shift the focus from distress (e.g., pain, anxiety, nausea) to the sensory details of a past pleasant experience. This usually distracts the patient enough so that some of the physical and emotional symptoms decrease. Guided imagery allows a practitioner to help the cancer patient through his or
her own past positive experiences or to create a positive image of the future along with the patient. It is a very effective therapy for symptom control. Guided imagery can be taught to nurses and family members so that they can affect the quality of the patient’s life. Guided imagery is contraindicated in a patient with cognitive impairment.

Creative Visualization

Creative visualization is the technique of using the imagination to create what one wants in life physically, emotionally, mentally, or spiritually. It is using the imagination to create a clear image of something one wishes to manifest. For the patient in the end stage of disease, visualization might take the form of imagining being at home again, feeling calm or more comfortable, visiting with a loved one, or going to that quiet still place within. The patient continues to focus on the idea or image regularly, giving it positive energy, until what is being visualized is achieved. It is preceded by relaxing into a deep meditative state. It is based on the following principles: the physical universe is energy (including individuals and their thoughts); energy is magnetic (energy of a certain quality attracts energy of a similar quality); form follows idea (the idea has energy that attracts and creates that form on the material plane; it magnetizes and guides the physical energy to flow into that form and eventually manifest on the physical plane); and the law of radiation and attraction (we attract into our lives what we think about). The point is that each individual is the constant creator of his or her life and has the means to bring himself or herself to a more comfortable place physically, emotionally, mentally, and spiritually. There is no evidence that creative visualization is curing cancer, but it can be very effective for symptom management.

Hypnosis
